Forward Guidance without Common Knowledge*

George-Marios Angeletos†  Chen Lian‡

October 6, 2017

Abstract

How does the economy respond to news about future policies or future fundamentals? Workhorse models answer this question by imposing common knowledge of the news and of their likely effects. Relaxing this assumption anchors the expectations of future outcomes, effectively leading to heavier discounting of the news. By the same token, general-equilibrium mechanisms that hinge on forward-looking expectations, such as the Keynesian feedback loop between inflation and spending, are attenuated. We establish these insights within a class of games (“dynamic beauty contests”) which nest the New-Keynesian model along with other applications. We next show how these insights help resolve the forward-guidance puzzle and offer a rationale for the front-loading of fiscal stimuli.

Keywords: Forward-guidance puzzle, fiscal stimuli, Keynesian multiplier, deflationary spiral, incomplete information, higher-order uncertainty, coordination, beauty contests.

---

1 Introduction

How does the economy respond to news about future policies and future fundamentals? Think, for example, of forward guidance, that is, of news about future monetary policy. Such news are meant to influence current economic activity, not only by shifting the term structure, but also by “managing expectations” of future outcomes such as output and inflation.¹

In macroeconomics and finance alike, this kind of forward-looking expectations is typically pined down by assuming that the agents have common knowledge of the state of the economy and of one another’s beliefs about the future. This imposes a certain “perfection” in how agents adjust their expectations of future economic outcomes, and their decisions, to any news about the future. We instead perturb this perfection and proceed to show how this anchors the relevant expectations and attenuates the general-equilibrium effects of news, especially when the latter regard events in the more distant future.

Our contribution proceeds in three steps. We start by revisiting the New-Keynesian model and by embedding its building blocks, the modern analogues of the IS and Philips curves, into a class of “dynamic beauty contests.” The latter stylize environments in which aggregate outcomes today—such as consumer spending, inflation, or asset prices—depend positively on expectations of the aggregate outcomes tomorrow.

Within this broader framework, we show that the absence of common knowledge anchors the expectations of future outcomes at a rate that increases with the horizon of the news. It is therefore as if the agents are discounting the influence of the distant future to current decisions more heavily than what seems rational. By the same token, general-equilibrium mechanisms that rest on the frictionless adjustment of forward-looking expectations are attenuated.

We finally return to the New-Keynesian model and apply our insights to the context of a liquidity trap. In this context, the absence of common knowledge anchors expectations of future inflation and income, attenuates the general-equilibrium effects that operate both within and across the two blocks of the model, lessens the forward-guidance puzzle, and offers a rationale for the front-loading of fiscal stimuli.

The friction. By “lack of common knowledge” or “incomplete information” we refer to situations in which the agents have an imperfect and idiosyncratic understanding of the exogenous impulses and of their equilibrium implications (think of policy news and of their effects on output and inflation). This could be the product of dispersed private information, which gets only imperfectly aggregated through markets. But it could also be the product of rational inattention (Sims, 2003; Tirole, 2015). In any event, the key is that, similarly to the literatures on “global games” and “beauty contests” (Morris and Shin, 1998, 2002, 2003; Angeletos and Lian, 2016b), we accommodate an imperfection in the coordination of beliefs and decisions by allowing for higher-order uncertainty (i.e., uncertainty about the beliefs and the decisions of others).

Removing common knowledge from the New-Keynesian model. Similarly to Mankiw and Reis (2002), Woodford (2003a) and Mackowiak and Wiederholt (2009), our setting allows the firms to have an imperfect and idiosyncratic understanding of the state of the economy. But it also adds two other features.

¹For evidence of how such news matter and for the difficulty of workhorse models to capture this evidence, see Campbell et al. (2012) and Del Negro, Giannoni and Patterson (2012).
First, we let the informational friction coexist with the Calvo friction so as to include a forward-looking element in the firms’ price-setting decisions. This links current inflation to expectations of future inflation, giving rise to a GE feedback mechanism within the supply block of the model.\footnote{Nimark (2008) also employs both frictions but pursues other objectives.}

Second, we assume that the consumers, too, to have an imperfect and idiosyncratic understanding of the state of the economy. This allows us to pay closer attention to the GE mechanism that operates within the demand block of the model and that regards the feedback loop between individual and aggregate spending for given real interest rates. This is a modern version of the Keynesian multiplier.\footnote{In the textbook version of the New-Keynesian model, the Keynesian multiplier reflects merely the dependance of consumption on permanent income. In more realistic settings, it contains additional mechanisms through which consumer spending today responds to expectations of economic conditions in the short to medium run, such precautionary motives, borrowing constraints, and “hand-to-mouth consumers” (Galí, López-Salido and Vallés, 2007; Kaplan, Moll and Violante, 2016; Auclert, 2017).}

We show how each of the two blocks of the model can be represented as a “dynamic beauty contest.” \footnote{More precisely, because both the average forecast of the future fundamental and the aggregate outcome are random variables, $\phi_T$ is defined as the coefficient of regressing the former on the latter. Think of this as the analogue of constructing an IRF.} With this term we refer to a class of games in which the aggregate outcome in any given period depends on the average expectation of that outcome in the future; such games nest, not only the two blocks of the New-Keynesian model, but also other applications, such as the dispersed-information asset-pricing models studied in Singleton (1987) and Allen, Morris and Shin (2006).

When agents share the same information and the same beliefs in all dates and all realizations of uncertainty (clearly, a very strong assumption), the obtained beauty contests reduce to the familiar equations of the textbook New-Keynesian model, namely the representative consumer’s Euler condition (a.k.a. dynamic IS curve) and the New-Keynesian Philips curve. Away from that benchmark, our representation helps unearth the role of the rich higher-order beliefs that are hidden beneath these deceptively simple equations.

**Attenuation and horizons in dynamic beauty contests.** Motivated by the previous result, in Section 5 we study how lack of common knowledge influences the equilibrium outcomes of aforementioned class of games. We focus, in particular, on the following question: how do outcomes in period $t$ (say, $t = 0$) vary with the current average forecast of the fundamental in period $t + T$?

Let $\phi_T$ denote the response of the former to the latter.\footnote{The sharpest version of these results is obtained under the assumption that the information structure remains constant between $t$ and $t + T$, at which point the true fundamental becomes known. Allowing for gradual learning does not invalidate the results, but adds certain complications that are discussed in due course.} We provide three main results.\footnote{The sharpest version of these results is obtained under the assumption that the information structure remains constant between $t$ and $t + T$, at which point the true fundamental becomes known. Allowing for gradual learning does not invalidate the results, but adds certain complications that are discussed in due course.} First, the absence of common knowledge reduces $\phi_T$ regardless of how precise the available information may be; we refer to this result as the “attenuation effect.” Second, this attenuation is increasing in $T$; we refer to this result as the “horizon effect.” Third, under a mild condition, $\phi_T$ becomes vanishing small relative to its common-knowledge counterpart (i.e., the attenuation effect increases without bound) as $T \to \infty$.

Let us sketch the proof of these findings. In our setting, there is a unique rational-expectations equilibrium, regardless of the information structure. Along this equilibrium, the aggregate outcome today can be expressed as a function of the first- and higher-order beliefs of the fundamental $T$ periods later. When common knowledge is imposed \textit{in addition} to the rational-expectations hypothesis, higher-order beliefs collapse to first-order beliefs, yielding the standard predictions. When, instead, common knowledge is broken,
higher-order beliefs move less than one-to-one with first-order beliefs. This explains the attenuation effect. The horizon effect, on the other hand, follows from the combination of the following two properties: that the covariation between first- and $h$-order beliefs falls with $h$; and that longer horizons raise the relative importance of higher-order beliefs. The first property is a whole-mark of higher-order uncertainty. The second follows from the fact that longer horizons involve more iterations of the best responses (the forward-looking, or Euler-like, equations of the model), which in turn map to beliefs of higher order. In short, iterating on the forward-looking equations of a model is akin to ascending the hierarchy of beliefs.

We complement these findings with an additional result, which helps recast $\phi_T$ as the solution to a representative-agent model in which the forward-looking expectations that regard aggregate (as opposed to own) outcomes are discounted by a factor that is directly related to the severity of the informational friction. It is therefore as if each agent is “myopic” vis-a-vis the future aggregate dynamics.

**Policy lessons.** In light of these broad insights, we revisit the predictions that the New-Keynesian model makes about monetary and fiscal policy in a liquidity trap. To do this, we must deal with the higher-layer beauty contest that obtains once we take into account the interaction of the two blocks of the model, as opposed to looking at each block in isolation from the other. The essence, however, remains the same.

We first consider the so-called forward guidance puzzle. This puzzle refers to the prediction of the New-Keynesian model that a credible promise to keep monetary policy lax far in the future can have an incredibly large effect on current economic activity. Suppose, in particular, that the nominal interest rate is pegged to zero between $t = 0$ and $t = T - 1$, for some known $T \geq 2$, due to a binding ZLB constraint. Because of this constraint, the Fed is unable to stimulate the economy by reducing its current policy rate. It can nevertheless try to achieve the same goal by committing to low interest rates at $t = T$ (or later), that is, after the economy has exited the liquidity trap and the ZLB constraint has ceased to bind. The standard New-Keynesian model predicts the effect of such increases with $T$ and explodes as $T \to \infty$: the longer the horizon at which the interest rate is lowered, the larger the effect on current aggregate spending. What is more, for plausible parameterizations, the effect is quantitatively large even for modest $T$.

These predictions are at odds with the available evidence (Del Negro, Giannoni and Patterson, 2012). They are also considered to be a priori counter-intuitive. In our view, this is largely because these predictions are driven by general-equilibrium mechanisms, which hinge on large adjustments in expectations of future outcomes and which work at “full capacity” when common knowledge is imposed.

To appreciate what we mean, consider the following question: how does an individual respond to news about a future interest-rate change that applies only to herself, as opposed to the entire economy? Answering this question helps isolate the direct or partial-equilibrium (PE) effect of future interest rates from their general-equilibrium (GE) effects. Because agents discount the future, the PE effect diminishes with $T$ and vanishes as $T \to \infty$. It follows that the aforementioned predictions are driven by GE mechanisms.

What are these GE mechanisms? Two of them have already been mentioned: one is the Keynesian multiplier that is hidden behind the IS curve, another is the feedback from future to current inflation that is hidden behind the NKPC. But there is an additional GE mechanism, which is operates across the two blocks.
of the model: the feedback loop between aggregate spending and inflation. Reducing the nominal interest rate at \( t = T \) causes inflation at \( t = T \). Because the nominal interest rate is pegged prior to \( T \), this translates to a low real interest rate between \( T - 1 \) and \( T \). This stimulates aggregate spending at \( T - 1 \), contributing to even higher inflation at \( T - 1 \), which in turn feeds to even higher spending at \( T - 2 \), and so on. Clearly, the cumulative effect at \( t = 0 \) increases with \( T \), which explains why the power of forward guidance also increases with \( T \)—indeed without bound—according to the New-Keynesian model.\(^6\)

Removing common knowledge attenuates all the three GE mechanisms, and the more so the larger \( T \) is, thus also reducing the gap between macroeconomic predictions and partial-equilibrium intuitions. To illustrate, suppose that each agent—be it a consumer or a firm—worries that any other agent may be unaware of the policy news with a 25% probability. Under a textbook parameterization of the New-Keynesian model, this “doubt” about the awareness of others causes the power of forward guidance to be reduced by about 90% at the 5-year horizon. Importantly, this attenuation is relative to the movements in expectations of interest rates. Our theory therefore helps explain why forward guidance may have a weak effect on expectations of inflation and income relative to its effect on the term structure of interest rates.\(^7\)

Turning to fiscal policy, the standard New-Keynesian model predicts that, in the presence of a binding ZLB constraint, a fiscal stimulus of a given size is more effective when it is back-loaded, i.e., when it is announced now but implemented later on.\(^8\) This prediction hinges on the same GE mechanisms and the same kind of forward-looking expectations as those that govern the power of forward guidance. A variant of the aforementioned results therefore applies: removing common knowledge reduces the magnitude of fiscal multipliers, and the more so the longer the horizon of the fiscal stimulus. To put it differently, our paper offers a rationale for the front-loading of fiscal stimuli.

**Layout.** The remainder of the paper is organized as follows. Section 2 discusses the related literature. Section 3 introduces our incomplete-information version of the New-Keynesian model. Section 4 nests the demand and supply blocks of the model within a class of dynamic beauty contests. Section 5 develop our key theoretical results regarding this class of games. Sections 6 and 7 work out the implications for, respectively, monetary and fiscal policy during a liquidity trap. Section 8 concludes the main text. The Appendices contain the proofs and few additional results.

\(^6\)This feedback loop is the flip-side of the “deflationary spiral” that helps the New-Keynesian model generate a sizable recession during a liquidity trap. The initial trigger is different, and the sign is reversed, but the GE mechanism at work is the same.

\(^7\)Let us emphasize that the issue at stake is *not* the credibility of the policy news (Bassetto, 2015) or the implied shift in the term structure of interest rates. For our purposes, the shifts in expectations of future interest rates are the exogenous impulses and the question of interest is how these impulses translate to movements in expectations of endogenous outcomes such as income and inflation. Also note that we rule out the confounding of news about one kind of fundamentals (say, about future interest rates) with news about another kind of fundamentals (say, about future growth potential). We are thus concerned with what Campbell et al. (2012) call “Odyssean” forward guidance. The alternative scenario, that of “Delphic” forward guidance, is emphasized in Andrade et al. (2015).

2 Related Literature

Our paper builds on the macroeconomic literature on incomplete information and beauty contests; see Angeletos and Lian (2016b) for a survey. Morris and Shin (2002), Woodford (2003a), Angeletos and Pavan (2007), Angeletos and La’O (2010, 2013), and Bergemann and Morris (2013) focus on static beauty contests, namely, settings in which the agents are not forward-looking and only have to forecast the concurrent actions of others. By contrast, Allen, Morris and Shin (2006), Bacchetta and van Wincoop (2006), Morris and Shin (2006), and Nimark (2008, 2017) study dynamic beauty contests, namely, settings in which the agents must forecast the future actions of others.

Our paper shares with the latter set of works the emphasis on forward-looking expectations; the class of beauty contests studied in these works is indeed a special case of the broader class studied here. But whereas these works focus on how outcomes vary with the learning that takes place over time, our paper focuses on how outcomes vary with the horizon of the events that the agents have to forecast. This explains our main theoretical contribution, which is to show how longer horizons translate to larger attenuation, holding constant the information structure. An additional contribution, which is crucial for our applied purposes, is to map the building blocks of the New-Keynesian model to the considered class of games.

By allowing for dispersed private information, we also connect to Lucas (1972). Note, however, that the latter abstracts from strategic complementarity and studies, in effect, a single-agent decision context featuring confusion between two kinds of fundamentals (namely, monetary shocks and relative-demand shocks). By contrast, we do not allow the news of future monetary policy to be confounded with news of other fundamentals. And whereas higher-order uncertainty is irrelevant in Lucas (1972), it is of absolute essence in our context.9

On the applied side, our paper adds to the recent literature on the forward-guidance puzzle. Del Negro, Giannoni and Patterson (2012) and McKay, Nakamura and Steinsson (2016b) seek to resolve the puzzle by modifying the PE effects of monetary policy: the one by introducing short horizons and adjustment costs (“internal habit”), the other by adding liquidity constraints. We make an orthogonal point: we keep the PE effects constant and, instead, dull the GE effects by introducing higher-order uncertainty. The considered friction is, not only conceptually distinct, but also better suited for explaining the sluggishness of expectations, as documented in Coibion and Gorodnichenko (2012, 2015) and Vellekoop and Wiederholt (2017).

Closely related in this regard is Wiederholt (2015). Similarly to ours, this paper stresses how higher-order uncertainty anchors inflation expectations and reduces the power of forward guidance. However, the modeling choices of that paper prevent one from detecting the higher-order beliefs that operate within each block of the New-Keynesian model.10 Most importantly, that paper does not study how the bite of higher-order uncertainty varies across horizons, which is the core theme of our paper.

---

9For a detailed explanation of why higher-order uncertainty is irrelevant in Lucas (1972), see Section 8.4 of Angeletos and Lian (2016b).

10On the supply side, the role of higher-order beliefs is shut down by assuming that the firms have common knowledge; and on the demand side, the attenuation of “income multiplier” is assumed away by letting the consumers can pool their income through insurance even though they cannot pool their information.
Chung, Herbst and Kiley (2015) and Kiley (2016) argue that some of the paradoxical predictions of the New-Keynesian model are resolved once the nominal rigidity is attributed to sticky information as in Mankiw and Reis (2002). But this is largely because these works shut down entirely the forward-looking nature of the firms’ price-setting decisions. These works also rule out information frictions among the consumers. They therefore do not share our insights regarding the effects of longer horizons, the anchoring of forward-looking expectations, and the attenuation of the associated GE effects.

Last but not least, our paper is related to Garcia-Schmidt and Woodford (2015), Farhi and Werning (2017), and Gabaix (2016). These works drop Rational Expectations from the New-Keynesian model. The first two consider Level-k Thinking (or a close cousin of it, “Reflective Equilibrium”); the third assumes that the agents apply a “cognitive discount” on the influence of shocks on future outcomes. By design, these concepts arrest the responsiveness of expectations and attenuate the associated GE effects. We instead show that similar effects are accommodated without the methodological sacrifice of dropping Rational Expectations, once one “liberates” that concept from auxiliary common-knowledge assumptions.

3 Framework

In this section, we introduce the framework used for the applied purposes of the paper. This is the same as the textbook New-Keynesian model (Woodford, 2003b; Galí, 2008), except that we remain more flexible about the structure of information and beliefs.

Consumers. There is a measure-one continuum of ex-ante identical households, or consumers, in the economy, indexed by $i \in I_c = [0, 1]$. The preferences of consumer $i$ are given by

$$U_0 = \sum_{t=0}^{+\infty} \beta^t U(c_{i,t}, n_{i,t}),$$

where $c_{i,t}$ and $n_{i,t}$ denotes her consumption and labor supply at period $t$, $\beta = e^{-\rho} \in (0, 1)$ is the discount factor, and $U$ is the per-period utility function. The latter is specified as $U(c, n) = \frac{1}{1-\frac{1}{\sigma}} c^{1-1/\sigma} - \frac{1}{1-\rho} n^{1+\epsilon}$, where $\sigma > 0$ is the elasticity of intertemporal substitution and $\epsilon > 0$ is the inverse of the Frisch elasticity. The budget constraint in period $t$ is given, in nominal terms, by the following:

$$p_t c_{i,t} + a_{i,t} = R_{t-1} a_{i,t-1} + p_t (w_{i,t} n_{i,t} + e_{i,t}),$$

where $p_t$ is the price level in period $t$, $a_{i,t}$ is the household’s nominal saving in that period, $R_{t-1}$ is the nominal gross interest rate between between $t - 1$ and $t$, and, finally, $w_{i,t}$ and $e_{i,t}$ are, respectively, the real wage and the real dividends received in period $t$. (The wage and the dividend are allowed to be household-specific for reasons that will be explained shortly.) We finally denote aggregate consumption by $c_t = \int_{I_c} c_{i,t} di$, aggregate labor by $n_t = \int_{I_c} n_{i,t} di$, and so on.

\footnote{Our approach seems also better suited for addressing the available evidence on expectations; see the discussion in page 5.}
Firms. There is a measure-one continuum of ex-ante identical firms, indexed by \( j \in \mathcal{I}_f = (1, 2] \). Each of these firms is a monopolist that produces a differentiated intermediate-good variety. The output of firm \( j \) is denoted by \( y_j^t \), its nominal price is denoted by \( p_j^t \), and its realized profit by \( e_j^t \). The technology is assumed to be linear in labor and productivity is fixed to one, so that

\[
y_j^t = l_j^t, \tag{3}
\]

where \( l_j^t \) is the labor input. These intermediate goods are used by a competitive sector as inputs in the production of the final good. The technology is CES with elasticity \( \varsigma \). Aggregate output is thus given by

\[
y_t = \left( \int_{I_f} \left( y_j^t \right)^{\varsigma - 1} \, dj \right)^{\frac{1}{\varsigma - 1}}, \tag{4}
\]

The corresponding price index—that is, the price level—is denoted by \( p_t \).

Sticky Prices. We introduce nominal rigidity in the usual, Calvo-like, fashion: in each period, a randomly selected fraction \( \theta \in (0, 1] \) of the firms must keep their prices unchanged, while the rest can reset them.

Stochasticity and Monetary Policy. For the time being, we refrain from making any specific assumption about either the underlying stochasticity or the monetary policy. We only note that the exogenous state of Nature may contain arbitrary news about future interest rates (think of forward guidance) and may induce rich higher-order uncertainty. We fill in the details in due course.

Rational Expectations and Common Knowledge. Throughout, we maintain the standard solution concept, namely, Rational Expectations Equilibrium (REE). We nevertheless depart from standard practice by making sure that the agents lack common knowledge.

In abstract games, such as those studied in Morris and Shin (2002, 2003), lack of common knowledge can be directly imposed by endowing each agent with exogenous private information. In applications, however, there is the complication that market signals, such as prices, aggregate the information that is dispersed among the agents. To preserve the absence of common knowledge, we can either make sure there is “noise” in the available market signals (Grossman and Stiglitz, 1980), or assume that the observation of all the variables—including the available market signals—is contaminated with idiosyncratic noise due rational inattention (Sims, 2003).

As discussed in Section 5, these “details” are not central to the developed arguments: what is key is the absence of common knowledge, and the resulting anchoring of the expectations that the agents form about the response of the economy to any given policy shift, not the precise manner in which this friction is engineered and preserved along the equilibrium. We follow the first approach in building our incomplete-information version of the New-Keynesian model only for a “pedagogical” reason: to make clear that our results are robust to allowing the consumers to have perfect knowledge of their own income, the firms to have perfect knowledge of their own demand and supply conditions, and everybody to have perfect knowledge
of the current prices and interest rates.\footnote{That is, for every $t$, we allow we allow each consumer $i$ to have private knowledge of $(w_{i,t}, e_{i,t}); we allow each monopolist $j$ to have private knowledge of $(w_{j,t}', \mu_{j,t}'); and we finally allow $R_t$ and $(p_{j,t}')_{j \in [0,1]}$ to be commonly known.} We nevertheless also like the second approach because it bypasses the need for “auxiliary shocks” and facilitates the re-interpretation of the assumed friction as the product of the cognitive limitations of the agents, or as of form of “bounded rationality.”

The auxiliary shocks. We conclude this section by describing the auxiliary shocks, and the associated informational assumptions, that permit us to apply the first of the aforementioned two modeling approaches. Take any period $t$ and let $w_t$, $e_t$, and $\mu_t$ denote, respectively, the average real wage, the average firm profit, and the average markup in the economy. The real wage and the dividend received by consumer $i$ at $t$ are given by, respectively, $w_{i,t} = w_{i} \xi_{i,t}$ and $e_{i,t} = e_{i} \zeta_{i,t}$, where $\xi_{i,t}$ and $\zeta_{i,t}$ are i.i.d. across $i$ and $t$, independent of one another, and independent of any other random variable in the economy. On the other hand, the real wage paid by firm $j$ is $w_{j,t}' = w_{j} u_{j,t}'$, and the markup charged by it is $\mu_{j,t}' = \mu_{j} \nu_{j,t}'$, where $u_{j,t}'$ and $\nu_{j,t}'$ are i.i.d. across both $j$ and $t$, independent of one another, and independent of any other random variable in the economy. One can interpret $u_{j,t}'$ and $\nu_{j,t}'$ as idiosyncratic shocks to a firm’s marginal cost and her optimal markup, and $\xi_{i,t}$ and $\zeta_{i,t}$ as idiosyncratic shocks to a household’s labor and financial income.\footnote{To simplify the exposition, we treat the aforementioned shocks as exogenous. Yet, it is not hard to see how the “missing micro-foundations” could be filled in. For instance, Angeletos, Iovino and La’O (2016) engineer the desired firm-specific markup shocks by allowing for good-specific shocks that shift the elasticity of the demand faced by each monopolist. Similarly, the desired household- and firm-specific wage shocks could be justified as follows. First, let the the households (workers) to have idiosyncratic taste shocks, which affect their supply of labor, and the firms to have idiosyncratic productivity shocks, which affect their demand for labor. Next, split the economy in a large set of decentralized labor markets (“islands”), indexed by $m$. Finally, assume that the workers and the firms are randomly allocated to one of these markets and that this random allocation is such that the average taste or productivity shock within any given market is non-zero (even though the average across markets is zero). The market-specific wage variation that obtains in this variant setting justifies the kind of household- and firm-specific wage shocks assumed above.}

As explained already, the modeling role of all these shocks is to “noise up” the information that each individual agent—be it a consumer or a firm—can extract from the available market signals about the underlying shifts in monetary policy and, most crucially, about the responses of other agents. In particular, the idiosyncratic wage shocks noise up the information that the consumers and the firms extract from, respectively, their labor income and their labor costs; the idiosyncratic markup shock guarantees that firms may lack common knowledge of the aggregate markup shock even though each one knows its own mark; and finally the aggregate markup shock guarantees that the price level (or the inflation) can be perfectly observed and nevertheless not reveal the underlying policy shifts. In our view, all these assumptions are highly plausible; rational inattention could substitute for them, but it could also complement them.

Log-linearization. To keep the analysis tractable, we work with the log-linearization of the model around a steady state in which inflation is zero and the nominal interest rate equals the natural rate (i.e., $\beta R = 1$). With abuse of notation, we henceforth reinterpret all the variables as the log-deviations from their steady state counterparts. We also let the means of the (logs of the) idiosyncratic shocks be zero.
4 Deconstructing the New-Keynesian Model into Two Beauty Contests

In this section, we develop our beauty-contest representation of the New-Keynesian model. Apart from facilitating the subsequent analysis, this representation clarifies how the applied New-Keynesian literature imposes a certain mapping from the expectations of exogenous fundamentals to the expectations of endogenous outcomes. This mapping hinges, not only the assumed micro-foundations in terms of preferences, technologies, and market structures, but also, and quite critically, on the combination of rational expectations with complete information (and therefore with a common belief about the state of the economy). From this perspective, our contribution boils down to understanding how this mapping is modified once the latter assumption is relaxed.

The two beauty contests. We let \( \pi_t = p_t - p_{t-1} \) denote the period-\( t \) inflation rate and study the joint determination of \( \pi_t \) and \( c_t \) (or, equivalently, of \( \pi_t \) and \( y_t \)). The next result establishes that, regardless of the information structure, the equilibrium values of these variables can be understood as the joint solution to two fixed-point problems, one for the demand block (consumers) and another for the supply block (firms). After stating the result and explaining its derivation, we discuss how these fixed-point problems can be interpreted as “beauty contests” and elaborate on the usefulness of this interpretation.

**Proposition 1 (Beauty Contests)** In any equilibrium, and regardless of the information structure, the following properties are true. First, aggregate spending satisfies

\[
    c_t = -\sigma \sum_{k=1}^{+\infty} \beta^{k-1} \bar{E}^c_t [r_{t+k}] + \frac{1-\beta}{\beta} \left\{ \sum_{k=1}^{+\infty} \beta^k \bar{E}^c_t [c_{t+k}] \right\},
\]

where \( \bar{E}^c_t [\cdot] \equiv \int_{\mathbb{I}_c} E_{i,t}[\cdot] di \) denotes the average expectation of the consumers and \( r_t = R_{t-1} - \pi_t \) denotes the realized real interest rate between \( t - 1 \) and \( t \). Second, inflation satisfies\(^{14}\)

\[
    \pi_t = \sum_{k=0}^{+\infty} (\beta \theta)^k \bar{E}_t^f [mc_{t+k}] + \frac{1-\theta}{\theta} \sum_{k=1}^{+\infty} (\beta \theta)^k \bar{E}_t^f [\pi_{t+k}] + \mu_t,
\]

where \( \bar{E}_t^f [\cdot] \equiv \int_{\mathbb{I}_f} E_{j,t}[\cdot] dj \) denotes the average expectation of the firms, \( mc_{t+k} = \kappa y_{t+k} \) is the real marginal cost in period \( t + k \), and \( \kappa \equiv \frac{(1-\theta)(1-\beta\theta)(\epsilon+1)}{\beta} \geq 0 \). Finally, \( y_t = c_t \).

Condition (5) is a general-equilibrium variant of the textbook version of the Permanent Income Hypothesis. It follows, essentially, from log-linearizing the individual consumption functions, aggregating across all consumers, and using market clearing in the product, labor, and debt markets. It gives current aggregate consumption as an increasing function of the consumers’ average expectation of the future path of aggregate income, which in equilibrium coincides with future aggregate consumption, and as a decreasing function of the expected path of the real interest rates.

\(^{14}\)To economize notation, when we transiting from (7) to (6), we rescale the markup shock: the \( \mu_t \) that appears in (6) equals \( \frac{\mu_t}{1-\beta} \) times the original \( \mu_t \).
Condition (6), on the other hand, follows from aggregating the optimal reset prices of the firms. To see the logic, recall that the optimal reset price of any given firm $j \in I_f$ is given by her expected discounted present value of her current and future nominal marginal cost:

$$p_t^* = (1 - \beta \theta) \left\{ mc_t^j + pt + \sum_{k=1}^{+\infty} (\beta \theta)^k E_{j,t} \left[ mc_{t+k}^j + p_{t+k} \right] \right\} + (1 - \beta \theta) \mu_t^j,$$

where $E_{j,t} [\cdot]$ denotes the firm’s expectation in period $t$, $mc_t^j$ is its real marginal cost in period $t$, and $\mu_t^j$ is its (exogenous) markup shock. Aggregating this condition across all the firms that get to reset their prices in period $t$, and using the fact that the resulting inflation is $\pi_t = (1 - \theta) (p_t^* - p_{t-1})$, where $(1 - \theta)$ is the fraction of firms that reset their prices and $p_t^* \equiv \int_{I_f} p_t^* \, dj$ is the average reset price, we get condition (6).

For our purposes, the key observation is that conditions (5) and (6) can be interpreted as a pair of dynamic beauty-contest games, one capturing the “demand block” of the New-Keynesian model and another capturing its “supply block.” Let us elaborate.

Consider first the aggregate behavior of the consumers and, momentarily, treat the process for the real interest rate as exogenous. Condition (5) then defines a game in which the players are the consumers, the actions are the consumers’ spending levels at different periods, and the “fundamental” is the path of real interest rates. A dynamic strategic complementarity is present in this game because the optimal spending of each consumer depends on her expectation of her future income, which in turn depends on the spending decisions of other consumers. Intuitively, when a consumer expects the others to spend more in the future, she expects her own income to be high, and finds it to spend more now. Condition (5) therefore isolates the strategic complementarity that operates within the demand block of the model and that encapsulates the GE mechanism that we refer to as the “income multiplier.”

Consider next the aggregate behavior of the firms and, momentarily, treat the process of the aggregate real output and, hence, of the average real marginal cost as exogenous. Condition (6) then defines a game in which the players are the firms, the actions are the prices, and the “fundamental” is the path of the average real marginal cost. A dynamic strategic complementary is present in this game because the optimal reset price of a firm depends on her expectation of future real marginal costs and of future price levels, which in turn depend on the pricing decisions of other firms. Intuitively, when firms expect inflation to be high, they also expect their nominal marginal costs to be high; they therefore find it optimal to set higher nominal prices when given the option to adjust, contributing to higher inflation today. Condition (6) therefore isolates the strategic complementarity that operates within the supply block.

The preceding discussion looks at each block of the model in isolation from the other. The interaction of the two blocks can be understood as a “meta-game” among the consumers and the firms. This meta-game

---

15In the simple version of the New-Keynesian model that we employ in this paper, this multiplier reflects merely the dependence of consumption on permanent income. In more realistic versions, it contains additional mechanisms via which aggregate demand responds to expectations of economic conditions in the short to medium run, such as precautionary motives or the feedback from expectations of economic activity to housing prices, and thereby to borrowing constraints and aggregate spending. We would like to think of our beauty-contest representation of the demand block as a proxy for this kind of forces as well.
embeds an additional form of strategic complementary, one that operates between the two groups of agents as opposed to within them. Intuitively, the consumers find it optimal to spend more when they expect future inflation to be high, because high inflation means low real returns to saving; and, symmetrically, the firms find it optimal to inflate more when they expect aggregate spending to be high, because high aggregate output means high marginal costs. It is this kind of strategic complementarity, or GE mechanism, that we refer as the “inflation-output feedback.”

**From the beauty contests to the Euler condition and the NKPC.** Before proceeding to the core of our paper, it is useful to relate our somewhat exotic representation of the New-Keynesian model to its more familiar, textbook treatments.

Since Proposition 1 holds true regardless of the information structure, it has to nest the standard version of the New-Keynesian model as a special case. Indeed, suppose that information is complete, namely, that the agents share the same expectations about all the relevant future variables (interest rates, inflation, income) in all periods and all states of Nature. In this case, we have that $E_{t,i}[\cdot] = E_t[\cdot]$ for every consumer $i \in I_c$ and every firm $i \in I_f$ and, therefore, $E_t^c[\cdot] = E_t^f[\cdot] = E_t[\cdot]$, where $E_t[\cdot]$ denotes the rational expectation conditional on all information in the economy available at period $t$ (aka, the information of the representative agent). Using this fact along with condition (5), we can express the period-$t$ spending as follows:

$$c_t = -\sigma E_t[r_{t+1}] + (1 - \beta) E_t[c_{t+1}] - \sigma \sum_{k=2}^{+\infty} \beta^{k-1} E_t[r_{t+k}] + \frac{1 - \beta}{\beta} \sum_{k=2}^{+\infty} \beta^k E_t[c_{t+k}].$$

Next, using Law of Iterated Expectations, we can rewrite the above as

$$c_t = -\sigma E_t[r_{t+1}] + (1 - \beta) E_t[c_{t+1}] + \beta E_t \left[ -\sigma \sum_{k=1}^{+\infty} \beta^{k-1} E_{t+1}[r_{t+1+k}] + \frac{1 - \beta}{\beta} \sum_{k=1}^{+\infty} \beta^k E_t[c_{t+1+k}] \right].$$

But now note that, from condition (5), the term inside the big brackets equals $c_{t+1}$. It follows that, when information is complete, condition (5) can be restated in recursive form as

$$c_t = -\sigma E_t[r_{t+1}] + E_t[c_{t+1}],$$

which is the familiar Euler condition. Similarly, condition (5) can be reduced to

$$\pi_t = mc_t + E_t[\pi_{t+1}] + \mu_t,$$

which is the familiar NKPC.

We conclude that the “missing link” between the textbook representation of the New-Keynesian model and the less familiar representation offered in Proposition 1 is the assumption of complete information (or

---

16Note that the argument made here restricts the information to be common but allows it to be otherwise arbitrary.
common knowledge). Without this assumption, the Law of Iterated Expectations cannot be applied to the “average” agent in the economy despite the imposition of rational expectations and, as a result, the beauty contests seen in conditions (5) and (6) cannot be reduced to, respectively, the representative consumer’s Euler condition and the NKPC. As we elaborate in the rest of the paper, this elementary observation has profound implications for what the theory predicts about the response of the economy to exogenous impulse, such as to news about future interest rates or future government spending.

**PE, GE, and Higher-Order Beliefs.** Inspecting condition (5) reveals the following basic point: holding constant the expectations of inflation and aggregate spending, a one-unit reduction in \( E_t[r_{T+1}] \) raises \( y_t \) by \( \beta^{T-t} \sigma \). This effect can be interpreted as the PE effect of forward guidance.\(^{17}\) Note that this effect decays with the horizon \( T \), due to discounting. By contrast, as explained in Section 6, the overall macroeconomic effect of forward guidance increases with \( T \) (at least when the forward guidance is common knowledge), due to the GE effects that run both within and across the two blocks of the model. A similar point applies to fiscal multipliers, once we add shocks to government spending (7).

Some recent works, such as Del Negro, Giannoni and Patterson (2012) and McKay, Nakamura and Steinsson (2016a,b), have studied realistic modifications of the New-Keynesian model that help reduce the aforementioned PE effect. We are instead concerned with the GE effects. As explained in the rest of the paper, such GE effects can be recast in terms of higher-order beliefs. Doing so helps understand how the macroeconomic effects of forward guidance or other news about the future hinge on the degree of common knowledge in the economy, regardless of how large or small the underlying PE effects are.

### 5 Dynamic Beauty Contests: Attenuation and Horizon Effect

In the previous section, we showed how we can represent each block of the New-Keynesian model as a dynamic beauty contest. In this section, we study a more abstract class of beauty contests that nests the two blocks of our New-Keynesian model along with other applications, such as the asset-pricing model of Singleton (1987), Allen, Morris and Shin (2006) and Nimark (2017). This permits us to sidestep the underlying micro-foundations and to illustrate in a transparent manner the two broader insights of our paper: (i) how the absence of common knowledge anchors forward-looking expectations and attenuates GE mechanisms; and (ii) how this attenuation increases with the horizon at which these mechanisms operate.\(^{18}\)

---

\(^{17}\)Strictly speaking, this is the PE effect plus the “within-period” GE effect, namely, the feedback effect between aggregate spending and the contemporaneous level of income. This effect, however, vanishes as the length of the time interval shrinks to zero, which justifies the interpretation of \( \beta^{T-t} \sigma \) as the PE effect.

\(^{18}\)By sidestepping the micro-foundations, we do not only speak to a larger class of environments, but also abstract from the kind of auxiliary shocks that were necessary before in order to limit the endogenous aggregation of information through markets. This rules out the possibility that agents confuse one kind of fundamental for another (say, the news about future monetary policy with news about the idiosyncratic components of wage and markups), isolates the role of higher-order uncertainty about the fundamental of interest, and clarifies why our contribution is entirely orthogonal to that of Lucas (1972).
The beauty contest. Time is discrete, indexed by $t \in \{0, 1, \ldots\}$, and there is a continuum of players, indexed by $i \in [0, 1]$. In each period $t$, each agent $i$ chooses an action $a_{i,t} \in \mathbb{R}$. We denote the corresponding average action by $a_t = \int_0^1 a_{i,t} \, di$ and let $\Theta_t \in \mathbb{R}$ denote an exogenous fundamental that becomes known in period $t$. We specify the best response of player $i$ in period $t$ as follows:

$$a_{i,t} = \Theta_t + \gamma E_{i,t} [a_{i,t+1}] + \alpha E_{i,t} [a_{t+1}], \quad (10)$$

where $\alpha, \gamma > 0$ are fixed parameters. Note that a player’s optimal action in any given period depends on her expectation of both her own and the aggregate action in the next period. The former effect is parameterized by $\gamma$, the latter by $\alpha$.

By iterating the above best response, aggregating across $i$, and letting $E_t[\cdot]$ denote the average expectation in period $t$, we reach the following representation of the considered beauty contest:

$$a_t = \Theta_t + \gamma \left\{ \sum_{k=1}^{+\infty} \gamma^{k-1} E_t[\Theta_{t+k}] \right\} + \alpha \left\{ \sum_{k=1}^{+\infty} \gamma^{k-1} E_t[a_{t+k}] \right\} \quad \forall t \geq 0 \quad (11)$$

This is the key equation we work with in the sequel. It relates the aggregate outcome in any given period to the concurrent fundamental, the average forecasts of the future fundamentals, and the average forecasts of the future aggregate outcomes.

When all agents share the same information, so that $E_t[\cdot] = E_t[\cdot]$ is the rational expectation of a representative agent, we can use the Law of Iterated Expectations to restate condition (11) as follows:

$$a_t = \Theta_t + \delta E_t[a_{t+1}] \quad \forall t \geq 0. \quad (12)$$

where $\delta \equiv \gamma + \alpha$. The above can be thought of as an aggregate-level Euler condition and $\delta$ as the “effective” discount factor that governs how much current outcomes depend on expectations of future outcomes. This dependence combines two distinct effects: a direct or PE effect that is parameterized by $\gamma$ and that regards what each agent expects herself to do in the future, and an indirect or GE effect that is parameterized by $\alpha$ and that regards what each agent expects the others to do. Yet, by looking at equation (12) alone, it is impossible to tell these two effects apart. This explains why it is important to “open up” this equation to (11), just as we did with the representative consumer’s Euler condition and the NKPC in the previous section.

Interpretation. Condition (11) directly nests the supply block of our New-Keynesian model: just interpret $\Theta_t$ and $a_t$ as, respectively, the real marginal cost and inflation, and set $\gamma = \beta \theta$ and $\alpha = \beta (1 - \theta)$. Similarly, to nest the demand block, interpret $\Theta_t$ as the real interest rate scaled by the elasticity of inter-temporal substitution, interpret $a_t$ as the aggregate level of spending, and set $\gamma = \beta$ and $\alpha = 1 - \beta$. Moving to a
completely different application, consider the class of incomplete-information asset-pricing models studied in Singleton (1987), Allen, Morris and Shin (2006), Bacchetta and van Wincoop (2006), and Nimark (2017). These models feature a single asset (“stock market”) and overlapping generations of differentially informed traders. The equilibrium asset price is shown to satisfy the following condition:

\[ p_t = d_t - s_t + \beta \bar{E}_t[p_{t+1}], \]

where \( p_t \), \( d_t \), and \( s_t \) denote the period-\( t \) price, dividend, and supply, respectively, and \( \bar{E}_t[\cdot] \) is the average expectation of the period-\( t \) traders. The above can be nested in condition (11) by letting \( \Theta_t = d_t - s_t \), \( a_t = p_t \), \( \alpha = \beta \) and \( \gamma = 0 \). \(^{21}\) This indicates, not only the likely broader applicability of the insights we develop in the rest of this section, but also that the aggregate outcome \( a_t \) can be a market-clearing price in a Walrasian setting rather than the average action of a set of players.

**The question of interest.** How does aggregate spending respond to news about future real interest rates? How does inflation respond to news about future real marginal costs? How do asset prices respond to news about future dividends? In the rest of this section, we seek to answer this kind of questions without taking a specific stand on how precise or credible the available news is, or how exactly it has to be modeled. We achieve this by focusing on how the aggregate outcome covaries with the concurrent forecasts of future fundamentals, and by abstracting from the exact source and magnitude of the variation in these forecasts.

More specifically, we fix an arbitrary \( T \geq 2 \) and isolate the role of first- and higher-uncertainty about the period-\( T \) fundamental, \( \Theta_T \), by shutting down the uncertainty about the fundamentals in any other period. Without any loss, we then let \( \Theta_t = 0 \) for all \( t \neq T \) and treat \( \Theta_T \) as the only random fundamental. We also anchor the beliefs of the aggregate outcome “at infinity” by imposing that \( \lim_{k \to \infty} \gamma^k E_{t,t}[a_{t+k}] = 0 \) with probability one. This is akin to ruling out infinite-horizon bubbles and can be justified either by letting the game end at any finite period \( T' > T \), or by imposing that \( \gamma < 1 \) and that \( a_t \) is bounded. We finally state the question of interest as follows: how does \( a_0 \), the current outcome, covaries with \( \bar{E}_0[\Theta_T] \), the current forecasts of the future fundamental?\(^{22}\)

**Complete vs Incomplete Information.** In what follows, we study how the answer to the aforementioned question varies as we move from the complete-information benchmark to the more realistic scenario in which the agents face uncertainty about one another’s beliefs and actions. To fix language, and to rule out can assume that prices are completely rigid (\( \theta = 1 \)), fix inflation at zero, and let \( \Theta_t = -\sigma R_t \). For the more general case in which inflation is variable, we can either modify the model so that \( r_{t+1} \) is observed or nest the existing version of the demand block in the variant of (11) that replaces \( \Theta_t \) with \( \dot{E}_t[\Theta_t] \). The results developed in the sequel are robust to such modifications. \(^{21}\) The restriction \( \gamma = 0 \) means that the aggregate outcome today depends only on the average expectation of the aggregate outcome tomorrow, as opposed to the entire path of the aggregate outcome in the future. Relative to the more general case we study here, this restriction decreases dramatically the dimensionality of the higher-order beliefs that the aforementioned works had to deal with. The most essential difference, however, between these works and ours is that they focus on the effects of learning whereas we focus on the effects of different horizons. \(^{22}\) Setting \( \Theta_t = 0 \) for all \( t \neq T \) is equivalent to isolating the variation in hierarchy of beliefs about the period-\( T \) fundamental that is orthogonal to belief hierarchy about the fundamental in any other period. Our result can thus be read as an “orthogonalization” of the effects of different horizons. Without any loss, we also normalize the unconditional mean of \( \Theta_T \) to be zero.
trivial cases in which the incompleteness of information regards only variables that are immaterial for our purposes (e.g. sunspots), we introduce the following definitions.

**Definition 1** We say that information is complete, or that the agents have common knowledge of the available news, if $E_{i,t}[\Theta_T] = E_{j,t}[\Theta_T]$ with probability one for all $(i, j, t)$ such that $i \neq j$ and $t \leq T - 1$. (And when the converse is true, we say that information is incomplete.)

**Definition 2** We say that the agents are able to reach a consensus about the future trajectory of the economy if $E_{i,t}[a_\tau] = E_{j,t}[a_\tau]$ with probability one for all $(i, j, t, \tau)$ such that $i \neq j$ and $t < \tau \leq T$.

Note that the first notion regards the beliefs the agents hold about the exogenous fundamentals, whereas the second notion regards the beliefs the agents form about the endogenous outcomes. While conceptual distinct, the two notions become tied together under the rational-expectations hypothesis.

**Proposition 2** Along any rational-expectations equilibrium, lack of consensus about the future outcomes is possible only when information is incomplete.

This clarifies the modeling role, and our preferred interpretation, of the introduced friction. What is at stake here is not how precisely the agents can forecast the fundamentals (think of the Federal Funds Rate or the associated term structure), but rather the inability to coordinate their beliefs and their responses to the exogenous impulses (the news).

**The Frictionless Benchmark.** As a reference point for our subsequent analysis, we first answer the question of interest in the absence of the considered friction.

**Lemma 1** Suppose that information is complete. For all states of Nature,

$$a_t = \phi^*_T \cdot E_t[\Theta_T] \quad \forall t \leq T - 1,$$

where $\phi^*_T = \delta^T \equiv (\gamma + \alpha)^T$.

The scalar $\phi^*_T$ measures how much the aggregate outcome covaries with the average forecast of the fundamental $T$ periods later. This scalar is easily computed by iterating on condition (12), which is the Euler condition of the complete-information economy. Indeed, since $\Theta_t = 0$ for all $t \neq T$, we have $a_T = \Theta_T$ and $a_t = \phi^*_{T-t}E_t[\Theta_T]$ for every $t \leq T - 1$, where $\{\phi^*_{T-t}\}_{t=0}^{T-1}$ solves the following recursion:

$$\phi^*_{T-t} = \delta \phi^*_{T-t-1} \quad \forall t \leq T - 1,$$

with “terminal” condition $\phi^*_0 = 1$. It follows that $\phi^*_T = \delta^T$, where, recall, $\delta \equiv \gamma + \alpha$ and where $\gamma$ and $\alpha$ parameterize, respectively, PE and GE effects.
The exact interpretation of $\phi_T^*$ and its magnitude depend, of course, on the application under consideration. Consider, for example, the demand block of the New-Keynesian model, in isolation of the supply block. In this context, $\phi_T^*$ measures the response of aggregate spending in period 0 to the concurrent expectation of the real interest rate in period $T$, holding constant the expectations of the real interest rate in all other periods. In the representative-agent version of the model, this object is the same regardless of $T$; this can readily be seen by iterating the Euler condition of the representative consumer. In the heterogeneous-agent variant studied by McKay, Nakamura and Steinsson (2016a), on the other hand, the corresponding object is decaying with $T$, due to liquidity constraints. Alternatively, consider the supply block of the model, or the NKPC. In this context, $\phi_T^*$ is given by $\beta^T$ and measures the response of inflation to news about marginal costs in period $T$; this can been seen by iterating the NKPC. Finally, in Singleton’s asset-pricing model, $\phi_T^*$ measures the response of the period-0 asset price to news about dividends in period $T$.

What is of interest to us, however, is not how $\phi_T^*$ varies as we move from one complete-information application to another, but rather how it compares to its incomplete-information counterpart. We address this question in the rest of the section. But let us first note two key facts about $\phi_T^*$. First, $\phi_T^*$ is invariant to the precision of the information that is available at $t = 0$; Second, $\phi_T^*$ is the same regardless of whether the representative agent expects to receive additional information between $t = 0$ and $t = T$ or not.$^{23}$

**The Frictional Case.** We henceforth focus on the scenario in which the agents are unable to reach a perfect consensus about the response of the economy to any given news about the future fundamentals. This raises the delicate question of whether and how the level of higher-order uncertainty evolves over time. For the time being, we bypass this complication by making the following simplifying assumption.

**Assumption 1** *There is no learning between $t = 0$ and $t = T$, at which point $\Theta_T$ becomes commonly known.*

As noted a moment ago, learning is completely inconsequential in the complete-information benchmark. This is no more true when information is incomplete, for reasons discussed later. Nevertheless, Assumption 1 is a useful starting point for three reasons. First, it affords an otherwise general specification of the information structure and yields the sharpest version of our results. Second, it delineates our results from prior work that studies the implications of learning (Woodford, 2003a, Allen, Morris and Shin, 2006, Bacchetta and van Wincoop, 2006). Last but not least, it can be relaxed without compromising our main lessons.

Let us now fill in the remaining details. Having ruled out learning, we consider an otherwise arbitrary specification of the information structure. We first let a random variable $s$ encapsulate the realization of the fundamental $\Theta_T$ along with any other aggregate shock that influences the information and the beliefs of the agents; we refer to $s$ as the underlying state of Nature. We next represent the information of agent $i$ by a random variable $\omega_i$, which is itself correlated with $s$. Along with the fact that there is no learning, this means that, for all $t \leq T - 1$, $E_{i,t}[\cdot] = E_{i,0}[\cdot] = E[\cdot | \omega_i]$, where $E[\cdot | \omega_i]$ is the rational expectation conditional on $\omega_i$.

$^{23}$Clearly, these properties hinge on the linear structure of the best responses. Nonetheless, they are useful for our purposes because they guarantee that only higher-order uncertainty affects the elasticity of outcomes to news about future fundamentals.
We refer to $s$ as the aggregate state of Nature and to $\omega_i$ as the signal of agent $i$. Conditional on $s$, this signal is an i.i.d. draw from a fixed distribution, whose p.d.f. is given by $\phi(\omega|s)$. This signal therefore encodes the information that agent $i$ has, not only about the fundamental $\Theta_T$, but also about the entire state of Nature and thereby about the information and the beliefs of other agents; in short, it is the Harsanyi type of the agent. We finally assume that a law of large number applies in the sense that $\phi(\omega|s)$ is also the p.d.f. of the cross-sectional distribution of the signals in the population, when the realized aggregate state is $s$.

Because the state $s$ can be an arbitrary random variable, the considered specification allows for rich first- and higher-order uncertainty and nests a variety of examples that can be found in the literature. For instance, we may let the aggregate state be $s = (\Theta_T, u)$, where $\Theta_T \sim N(0, \sigma_0^2)$ and $u \sim N(0, \sigma_u^2)$ are independent of one another, and specify the signal as $\omega_i = (z, x_i)$, where $z = \Theta_T + u$, $x_i = \Theta_T + v_i$, and $v_i \sim N(0, \sigma_v^2)$ is independent of $s$ and i.i.d. across $i$. This case nests the information structure assumed in Morris and Shin (2002): each agent receives two signals about $\Theta_T$, a private one given by $x_i$, and a public one given by $z$. Alternatively, we may modify the aforementioned case by letting $\omega_i = (z_i, x_i)$, with $x_i$ as before and $z_i = z + \eta_i$, $\eta_i \sim N(0, \sigma_\eta^2)$. In this case, there is a public signal $z$, whose observation is, however, contaminated by idiosyncratic noise, perhaps due to rational inattention a la Sims (2003). As yet another example, we could let the aggregate state be $s = (\Theta_T, \sigma)$, where $\Theta_T \sim N(0, \sigma_0^2)$ and $\sigma \sim U[\underline{\sigma}, \bar{\sigma}]$, and specify the signal as $\omega_i = (x_i, \sigma_i)$, where $x_i = \Theta_T + v_i$, $v_i \sim N(0, \sigma_i^2)$, $\sigma_i \sim U[\sigma - \Delta, \sigma + \Delta]$, and $\Delta, \underline{\sigma}, \bar{\sigma}$ being known scalars such that $0 < \Delta < \underline{\sigma} < \bar{\sigma}$. In this case, some agents are better informed than others, plus each agent is uncertain about how informed or uninformed the other agents are.

**Higher-order beliefs.** An instrumental step towards addressing the question of interest is to understand the role of higher-order beliefs. Since $\Theta_t$ is fixed at zero for all $t \neq T$ and $\Theta_T$ becomes commonly known at $t = T$, we have $a_t = 0$ for all $t \geq T + 1$, $a_T = \Theta_T$, and, for all $t \leq T - 1$,

$$a_t = \gamma^{T - t} E_t [\Theta_T] + \alpha \sum_{k=1}^{T-t} \gamma^{k-1} E_t [a_{t+k}] . \tag{15}$$

By Assumption 1 (no learning), $E_t [\cdot] = E_0 [\cdot]$ for all $t \leq T - 1$. Using this fact, and iterating on the above condition, we reach the following lemma, which represents the period-0 outcome as a linear function of the concurrent average first- and higher-order expectations of $\Theta_T$.

**Lemma 2** For every $(\alpha, \gamma, T)$, there exist positive scalars $\{\chi_{h,T} \}_{h=1}^T$ such that, regardless of the information structure,

$$a_0 = \sum_{h=1}^T \left\{ \chi_{h,T} E^h_0 [\Theta_T] \right\} \tag{16}$$

where $E^h_0 [\cdot]$ is defined recursively by $E^1_0 [\cdot] = E_0 [\cdot]$ and $E^h_0 = E_0 [E^{h-1}_0 [\cdot]]$ for every $h \geq 2$.

The weights $\chi_{h,T}$ can be constructed in a recursive manner, as functions of $\alpha$, $\gamma$, $h$, and $T$ alone; see the Appendix for details. Here, we focus on the interpretation and the implications of Lemma 2.
Applied to the demand block of the New-Keynesian model, this lemma means that today's aggregate spending is determined by the hierarchy of beliefs about future real interest rates. Applied to the supply block, it means that today's inflation is determined by the hierarchy of beliefs about future real marginal costs. In prior work, this two kinds of higher-order beliefs are “swept under the carpet” because complete information lets higher-order beliefs collapse to first-order beliefs.

To see this point in the abstract context under consideration, note that when higher-order beliefs coincide with first-order beliefs condition (16) reduces to

$$a_0 = \left( \sum_{h=1}^{T} \chi_{h,T} \right) \cdot \tilde{E}_0[\Theta_T].$$

Along with Lemma 1, this also means that the complete-information outcome satisfies the following restriction:

$$\phi_T^* = \sum_{h=1}^{T} \chi_{h,T}. \tag{17}$$

When, instead, information is incomplete, higher-order beliefs no more coincide with first-order expectations. To understand how $a_0$ covaries with $\tilde{E}_0[\Theta_T]$, we must therefore understand both how higher-order beliefs covary with first-order beliefs and how the beliefs of different order load into $a_0$. We complete these tasks in the sequel—but first we state the ultimate lesson.

**Theorem 1** Suppose that information is incomplete. There exists a positive scalar $\phi_T$, which depends on both $T$ and the information structure, such that the following properties hold:

(i) For all states of Nature,

$$a_0 = \phi_T \cdot \tilde{E}_0[\Theta_T] + \epsilon, \tag{18}$$

where $\epsilon$ is either identically zero or is random but orthogonal to $\tilde{E}_0[\Theta_T]$.

(ii) The ratio $\phi_T / \phi_T^*$ is strictly less than 1.

(iii) The ratio $\phi_T / \phi_T^*$ is strictly decreasing in $T$.

Part (i) identifies $\phi_T$ as the incomplete-information counterpart of $\phi_T^*$. Part (ii) establishes that the absence of common knowledge reduces the extent to which the aggregate outcome covaries with the average forecast of the fundamental, regardless of how precise the latter is. We refer to this finding as the “attenuation effect”. Part (iii) establishes that this kind of attenuation increases with $T$: the longer the horizon, the larger the reduction in the responsiveness of the aggregate outcome to the forecasts of the fundamental relative to the frictionless benchmark. We refer to this finding as the “horizon effect.”

Let us now sketch the proof of the result. Part (i) is trivial: it follows directly from projecting $a_0$ on $\tilde{E}_0[\Theta_T]$ and letting $\phi_T$ be the coefficient of this projection and $\epsilon$ the residual. The latter captures any variation in higher-order beliefs that is orthogonal to the variation in first-order beliefs, such as the kind of “sentiment shocks” studied in Angeletos and La’O (2013).

To prove parts (ii) and (iii), note first that Lemma 2 implies that the following condition holds regardless of the information structure:

$$\phi_T = \sum_{h=1}^{T} \chi_{h,T} \beta_h \tag{19}$$
where \( \{ \chi_{h,T} \} \) are the same scalars as those appearing in Lemma 2 and

\[
\beta_h \equiv \frac{\text{Cov} \left( E_0^h[\Theta_T], E_0^1[\Theta_T] \right)}{\text{Var} \left( E_0^1[\Theta_T] \right)}
\]  

(20)
is the coefficient of the projection of \( E_0^h[\Theta_T] \) on \( E_0^1[\Theta_T] \), for any \( h \geq 1 \). When information is complete, \( E_0^h[\Theta_T] \) coincides with \( E_0^1[\Theta_T] \) for all \( h \) and all realizations of uncertainty, which in turn means that \( \beta^h \) is identically 1 for all \( h \). By contrast:

**Lemma 3** When information is incomplete, \( \beta_h \) is bounded in \((0, 1)\) for all \( h \geq 2 \) and is decreasing in \( h \).

In words, when information is incomplete, higher-order beliefs co-move less with first-order beliefs than lower-order beliefs. This result is easy to establish for the specific information structure studied in Morris and Shin (2002), but requires more work for the more general structure allowed here. It has a similar flavor as the result found in Samet (1998), which essentially states that higher-order beliefs are “anchored” by the common prior, but is distinct from it, because that result regards only the asymptotic properties of higher-order beliefs as \( h \to \infty \) and contains no information on whether the covariance between first- and \( h \)-order forecasts varies monotonically with \( h \).

Let us now go back to the proof of Theorem 1. Part (ii) now follows directly from the fact that \( \beta^h \in (0, 1) \), along with conditions (17) and (19). In a nutshell, \( \phi_T \) is less than \( \phi_T^+ \) simply because higher-order beliefs move less than one-to-one with first-order beliefs when, and only when, information is incomplete. Importantly, this has noting to do with how much the first-order beliefs themselves co-move with the fundamental.

**Corollary 1** Fix \((\alpha, \gamma, T)\). An incomplete-information economy features a lower response to expectations of future fundamentals (i.e., a lower \( \phi_T \)) than a complete-information economy, even if the agents have more precise information in the former than in the latter. In this sense, the standard modeling practice “overstates” the aforementioned response.

What remains to prove is part (iii), namely, the property that the attenuation of \( \phi_T \) relative to \( \phi_T^+ \) increases with the horizon. This follows from combining our earlier result that the covariation between first- and higher-order beliefs decreases with the belief order \( h \) (Lemma 3) with another result, which we establish next and which sheds light on how the horizon \( T \) affects the relative importance of higher-order beliefs in the period-0 outcome.

**Theorem 2** Fix \((\alpha, \gamma)\). For any \((h, T)\) such that \( 1 \leq h \leq T \), let \( s_{h,T} \) be the total weight on beliefs of order up to, and including, \( h \); that is, \( s_{h,T} \equiv \sum_{r=1}^{h} \chi_{r,T} \), where the \( \chi \)'s are the same coefficients as those appearing in condition (16). The ratio \( s_{h,T}/s_{T,T} \), which measures the relative contribution of the first \( h \) orders of beliefs to the aggregate outcome, strictly decreases with the horizon \( T \) and converges to 0 as \( T \to \infty \).

\textsuperscript{24}Obviously, for \( h = 1 \), we have \( \beta_1 = 1 \) regardless of the information structure.
This result is crucial (which is why it qualifies, at least in our eyes, to be called a “theorem”). Longer horizons increase the number of loops from future aggregate actions to current actions. But when one increases the number of loops, one is effectively walking down the hierarchy of beliefs: forecasting outcomes further and further into the future maps to forecasting the forecasts of others at higher and higher orders. This in turn explains why longer horizons increase the relative importance of higher-order beliefs. Part (iii) of Theorem 1 then follows from combining this finding with the fact that high-order beliefs themselves covary with less with first-order beliefs than what lower-beliefs.

To sum up: The “attenuation effect” \( \phi_T / \phi_T^* < 1 \) follows merely from the fact that incomplete information dampens the covariation of higher-order beliefs with first-order beliefs \( \beta_h < 1 \) for all \( h \). The “horizon effect” \( \phi_T / \phi_T^* \) decreases with \( T \); on the other hand, follows for the fact that this dampening is larger the higher the order of beliefs \( \beta_h \) decreases with \( h \) together with the fact that longer horizons raise the relative importance of higher-order beliefs (Theorem 2).

**The limit as** \( T \to \infty \). We now complement the preceding results by establishing that, as long as higher-order beliefs are sufficiently anchored in the sense made precise below, \( \phi_T \) becomes vanishingly small relative to its complete-information counterpart as the horizon gets larger and larger.

**Proposition 3 (Limit)** If \( \lim_{h \to \infty} \text{Var} \left( \hat{E}^h|\Theta_T \right) = 0 \), then

\[
\lim_{T \to \infty} \frac{\phi_T}{\phi_T^*} = 0,
\]

This result holds true regardless of whether \( \phi_T^* \) itself converges or explodes, which in turn depends on whether \( \delta \equiv \gamma + \alpha \) is lower or higher than 1. As it will become clear in the next section, the latter case, where \( \phi_T^* \) explodes, is directly relevant in the context of a liquidity trap.

To see how the result is obtained and to appreciate what it involves, note first that, by Theorem 1, the ratio \( \frac{\phi_T}{\phi_T^*} \) is strictly decreasing in \( T \) and bounded in \((0, 1)\). It follows that \( \frac{\phi_T}{\phi_T^*} \) necessarily converges to some \( \varphi \in (0, 1) \) as \( T \to \infty \). In the appendix we show that \( \varphi = \lim_{h \to \infty} \beta_h \), where \( \beta_h \) is defined as before. This fact is, essentially, a corollary of Theorem 2: in the limit as \( T \to \infty \), only the infinite-order beliefs matter. Establishing that \( \frac{\phi_T}{\phi_T^*} \) converges to zero as \( T \to \infty \) is therefore equivalent to establishing that \( \beta_h \) converges to zero as \( h \to \infty \). Clearly, a sufficient (in fact, also a necessary) condition for this to be the case is that \( \lim_{h \to \infty} \text{Var} \left( \hat{E}^h|\Theta_T \right) = 0 \).

This condition need not hold for every information structure, but can be said to be “generic” in the following sense. Take, as a reference point, the familiar case in which \( \Theta_T \) is Normal and the agents observe a noisy private signal and a noisy public signal as in Morris and Shin (2002). In this special case, it is straightforward to show that \( \varphi = \lim \beta^h \) is pinned down by the relative precision of the public signal and can be close to 1 if the public signal is precise enough. But now let us perturb this economy by allowing each agent’s observation of the public signal to be contaminated by (tiny) idiosyncratic noise, perhaps due to rational inattention or some other cognitive limitation. Then, \( \varphi = \lim_{h \to \infty} \beta^h \) is necessarily 0, even if the
The result given in Proposition 3 is therefore closely related to the uniqueness result in global games (Morris and Shin, 1998, 2003): the common thread between the two results is the disproportionate effect of the (very) high orders of belief and the resulting discontinuity in small perturbations of common knowledge. For our purposes, it offers a sharp illustration of how, in the class of dynamic beauty contests we are interested in, longer horizons map to beliefs of higher order and, thereby, to a larger attenuation effect.

An example and an equivalence result. The preceding analysis was heavy because we sought generality. We now present an example that simplifies the analysis by imposing an “exponential” structure on the hierarchy of beliefs. This example also serves two additional purposes: it offers a concrete interpretation of the information structure along the lines of the “news” literature; and it helps react to the lack of common knowledge as a certain form of myopia, or discounting.

For this example, we let \( \Theta_T = z + \eta \), where \( z \sim N(0, \sigma_z^2) \) and \( \eta \sim N(0, \sigma_\eta^2) \) are independent of one another. We interpret \( z \) as the component of \( \Theta_T \) that is realized at \( t = 0 \) and \( \eta \) as a residual that is realized at \( t = T \). Finally, we let the signal of agent \( i \) received at \( t = 0 \) be

\[
\omega_i = z + v_i,
\]

where \( v_i \sim N(0, \sigma_i^2) \) is i.i.d across \( i \) and orthogonal to both \( z \) and \( \eta \). We can then think of \( z \) as “news” about \( \Theta_T \) and \( v_i \) as an idiosyncratic noise in the observation, or interpretation, of this news by agent \( i \).

Regardless of its interpretation, the key property of this example is that it imposes an exponential structure in the belief hierarchy. By this we mean that, for every \( h \geq 2 \),

\[
\tilde{E}_0^h[\Theta_T] = \lambda \tilde{E}_0^{h-1}[\Theta_T],
\]

where \( \lambda \equiv \frac{\sigma_z^2}{\sigma_z^2 + \sigma_\eta^2} \in (0, 1) \). This scalar therefore controls the speed with which the covariation between first and \( h \)-order beliefs decay with \( h \). A lower \( \lambda \) captures a lower degree of common knowledge; the frictionless, complete-information, benchmark is nested in the limit as \( \lambda \to 1 \).

The following result can then be shown.

**Proposition 4 (Discounting)** The elasticity \( \phi_T \) in the incomplete-information economy described above is the same as the elasticity \( \phi^* \) in a representative-agent economy in which, for all \( t \leq T - 2 \), the Euler condition (12) holds with \( \delta \equiv \gamma + \alpha \) replaced by \( \delta' \equiv \gamma + \alpha \lambda \).

This result illustrates that, under appropriate conditions, the object of interest can be calculated with the same ease as in the complete-information benchmark. It also offers a sharp formalization of the idea that removing common knowledge causes the economy to act as if the representative agent is myopic and

\[\text{as noted earlier, this case is formalized by letting agent } i \text{ observe } z_i = z + \eta_i, \text{ where } z = \Theta_T + u \text{ is the underlying public signal and } \eta_i \text{ is the contaminating idiosyncratic noise. Our statement is that } \lim_{h \to \infty} \beta_h = 0 \text{ as long as } \text{Var}(\eta_i) \text{ is not exactly zero.}\]
discounts the future more heavily that what in the frictionless benchmark (the effective $\delta$ is also reduced). The extent of this kind of myopia is inversely related to $\lambda$, the degree of common knowledge.

The logic behind this "as if" result is simple. In the considered example, all the average higher-order forecast are linear transformations of the average first-order forecast. This guarantees that, for all $t \in \{1, ..., T-1\}$, the aggregate outcome can be expressed as a multiple of the average first-order forecast: $a_t = \phi_{T-t} E_0[\Theta_T]$, for some known scalar $\phi_{T-t}$. It follows that the prior-period average forecast of that outcome equals the same multiple of the average second-order forecast: $\bar{E}_{t-1}[a_t] = \phi_{T-t} \bar{E}_0^2[\Theta_T]$. And since $\bar{E}_0^2[\Theta_T] = \lambda E_0[\Theta_T]$, we conclude that $\bar{E}_{t-1}[a_t] = \lambda a_t$. It is therefore as if the average agent systematically underestimates the variation in the future aggregate outcome, which in turn explains the result in Proposition 4.

Clearly, the exact result relies on the particular information structure assumed above. The logic, however, applies more generally. As already mentioned, the key feature of the considered example is that $\lambda$ controls the speed with which $\beta_h$, the covariation between first and $h$-order beliefs, decays with $h$. The kind of myopia, or discounting, reported above is merely a manifestation of the more general property that $\beta_h$ decays with $h$. Propositions 1 and 4 are therefore mirror images of each other: saying that there is more attenuation at longer horizons is the same as saying that the agents are, effectively, myopic.

**Allowing for learning.** We now return to the role played by Assumption 1. Relaxing this assumption does not appear to invalidate the insights we have developed, but complicates the analysis and precludes us from establishing Theorem 1 for arbitrary information structures. This is due to the increased complexity of the kind of higher-order beliefs that emerge once information is changing between 0 and $T$.

To appreciate what we mean by this, note that the absence of learning (namely, $\bar{E}_t[\cdot] = E_0[\cdot]$ for all $t < T$) guarantees that the following properties hold for $h \in \{2, ..., T\}$ and any $\{t_2, t_3, ..., t_h\}$ such that $0 < t_2 < ... < t_h < T$:

$$E_0[\bar{E}_{t_2} \cdots [\bar{E}_{t_h}[\Theta_T] \cdots]] = E_0[\cdot]$$

That is, Assumption 1 allows us to collapse the "cross-period" higher-order beliefs to the "within-period" higher-order beliefs. This is the key step for obtaining the convenient representation of $\bar{a}_0$ in Lemma 2 and, thereby, for applying Lemma 3. Without Assumption 1, we must instead express $\bar{a}_0$ as a function of all the aforementioned kind of "cross-period" higher-order beliefs, which greatly complicates the analysis. Note, in particular, that there are $T-1$ types of second-order beliefs (namely, $E_0[\bar{E}_t[\cdot]]$ for all $t$ such that $1 \leq t \leq T-1$), plus $\frac{(T-1) \times (T-2)}{2}$ types of third-order beliefs, plus $\frac{(T-1) \times (T-2) \times (T-3)}{6}$ types of fourth-order beliefs, and so on. What is more, the correlation structure between first- and higher-order beliefs is more intricate, reflecting the anticipation of learning. Intuitively, the first-order belief $E_0[\Theta_{10}]$ can be less correlated with the second-order belief $E_0[\bar{E}_1[\Theta_{10}]]$ than with the third-order belief $E_0[\bar{E}_8[\bar{E}_9[\Theta_{10}]]]$ if there is little or no learning between periods 0 and 1 but a lot of learning between periods 1 and 8. While this possibility does not necessarily invalidate the take-home lessons of Theorem 1,\(^{26}\) it precludes us from extending these lessons to arbitrary forms of learning.

\(^{26}\)This possibility is indeed allowed in the cases studied in Appendix B, for which that theorem continues to apply.
It is possible, however, to overcome this caveat for two leading forms of learning studied in the literature. In one, we let the agents become gradually aware of $\Theta_T$, as in Mankiw and Reis (2002) and Wiederholt (2015). In the other, we allow the agents to receive a new private signal about $\Theta_T$ in each period prior to $T$, as in Woodford (2003a), Nimark (2008), and Mackowiak and Wiederholt (2009). In these two cases, we can not only recover Theorem 1, but also obtain a variant of Proposition 4. See Appendix B for details.

Also note that our Theorem 2, which establishes that longer horizons raise the relative importance of higher-order beliefs, follows directly from the best-response structure and is therefore independent of the information structure. This is suggestive of why our horizon effect may extend well beyond the aforementioned cases. In line with this idea, we are able to show that the result of Proposition 3, namely the property that $\phi_T$ becomes vanishingly small relative to $\phi_T^*$ as $T \to \infty$, extends to arbitrary forms of learning as long as the higher-order uncertainty remains bounded away from zero, in the sense made precise in Appendix B.

On the basis of these findings, we conclude that our lessons regarding the interaction of horizons and lack of common knowledge are robust to the introduction of learning. Two additional lessons, however, emerge once we take into account learning.

The first is that, holding the period-0 information constant, $\phi_T$ is closer to $\phi_T^*$ in the scenario in which subsequent learning is allowed relative to the scenario in which such learning is ruled out. Intuitively, the anticipation of a lower (higher) friction in the future eases (exacerbates) the friction in the present. Note that this effect hinges on the agents being forward-looking and is therefore absent in static beauty contests, such as those studied in Morris and Shin (2002), Woodford (2003a), and Angeletos and La’O (2010).

The second lesson is that, as time passes and agents accumulate more information, higher-order beliefs converge to first-order beliefs, causing the anchoring of the expectations and the attenuation of GE effects to decay with the lag of time since the news has arrived. Although this prediction is not a core theme of our paper, it is worth noting that it is consistent with the available evidence on the impulse responses of expectations to identified shocks (Coibion and Gorodnichenko, 2012; Vellekoop and Wiederholt, 2017). By contrast, this evidence seems incompatible with the theories developed in Gabaix (2016) and Farhi and Werning (2017): by design, these theories attenuate the response of expectations to shocks but do not allow this attenuation to decay with the lag since the shock has hit the economy.

**Rational Inattention.** We now briefly sketch how the considered friction can be recast as the product of rational inattention. We let $\Theta_T$ be Normally distributed and, to sharpen the exposition, we assume that $\Theta_T$ is realized at $t = 0$ (think of $\Theta_T$ as being itself the “news” about the future.) We next assume that the typical agents is unable to track $\Theta_T$ perfectly, due to rational inattention as in Sims (2003). Accordingly, in each period $t$, the action $a_{i,t}$ must be measurable in $\omega_i \equiv \{\omega_{i,\tau}\}_{\tau \leq t}$, where $\omega_{i,\tau}$ is a noisy signal received in period $\tau$. These signals are chosen optimally to be the agent, subject to certain constraints, which we describe next.

\footnote{Formally, consider the setting with learning studied in Appendix B, pick any $\tau \in \{1,...,T-2\}$, and look at the response of $a_i$ at $t = \tau$ rather than at $t = 0$. It is easy to check that this response increases with the precision of the information that arrives between $t = 0$ and $t = \tau$. A variant of this property is at the core of Woodford (2003a), Bacchetta and van Wincoop (2006), Nimark (2008, 2017), and Angeletos and La’O (2010): these papers show how, following any given innovation in the fundamentals, there is a large “wedge” between first- and higher-order beliefs, but this wedge decays as time passes and learning occurs.}
Following Woodford (2003a), Mackowiak and Wiederholt (2009) and others, we assume that the noise in $\omega_{i,\tau}$ is independent across $i$. This guarantees that all equilibrium outcomes are functions of $\Theta_T$ and, therefore, we can reduce the rational-inattention problem faced by each agent to the choice of a sequence of signals about $\Theta_T$. Finally, we let each agent $i$ choose her signals so as to minimize her the utility loss relative to full information subject to

$$I(\omega_{i,t}, \Theta_T | \omega_{i}^{t-1}) \leq \kappa^{RI},$$

where $I(\omega_{i,t}, \Theta_T | \omega_{i}^{t-1})$ is the (entropy-based) information flow between the period-$t$ signal and the underlying fundamental, conditional on the agent's past information, and $\kappa^{RI} > 0$ is an exogenous scalar. As usual, the interpretation of (21) is that it captures the agent's limited cognitive capacity.

As long as the prior about $\Theta_T$ is Gaussian and the objective function is quadratic, which is the case here, the optimal signal is also Gaussian. Furthermore, the noise in the signal has to be independent across periods, or else the agent could economize on cognitive costs, that is, relax the constraint in (21). These arguments are standard; see, e.g., (Mackowiak, Matejka and Wiederholt, 2017). The case we study here is actually far simpler than the one studied in that paper, because the relevant fundamental ($\Theta_T$) does not vary as time passes. We infer that the optimal signal at every $t \leq T - 1$ is given by

$$\omega_{i,t} = \Theta_T + v_{i,t},$$

where the noise $v_{i,t}$ is orthogonal to both $\Theta_T$ and $\{v_{i,\tau}\}_{\tau < t}$. Letting $\tau_t$ denotes the precision (i.e., the reciprocal of the variance) of this noise, we have that the period-$t$ information flow is given by

$$I(\omega_{i,t}, \Theta_T | \omega_{i}^{t-1}) = \frac{1}{2} \log_2 \left( 1 + \frac{\tau_t}{\varsigma_t} \right),$$

where $\varsigma_t$ denotes the precision of the agent’s prior in the beginning of period $t$; the latter is defined recursively by $\varsigma_0 = \sigma_0^{-2}$ and $\varsigma_{t+1} = \varsigma_t + \tau_t$ for $t \in \{0, \ldots, T - 1\}$. It follows that the information constraint (21) pins down the sequence $\{\tau_t\}_{t=0}^{T-1}$ as a function of $\delta$ and $\sigma_0^2$ alone.

All in all, the rational-inattention setting described above is therefore nested in one of the cases studied in Appendix B, where we allow the agents to receive a new private signal about $\Theta_T$ in each period. As already noted, Theorem 1 holds in this case. It follows that the attenuation and horizon effects documented in Theorem 1 can be readily recast as the consequences of rational inattention.

The exact version of this argument rests on $\Theta_T$ being the only source of uncertainty. It may therefore not extend to richer settings which feature multiple kinds of shocks and let the acquired signals confound information about different fundamentals. Notwithstanding this qualification, the point we have made here

---

28This assumption is standard in the literature, but does not necessarily follow from the foundations of rational inattention: the noise in the signals could be correlated across the agents. However, it is easy to verify that, as long as the “target action” of each agent depends on the average action in the economy, the noise cannot be perfectly correlated across the agents. That is, it has to be that the signals are contaminated with idiosyncratic noise and, therefore, that the agents face higher-order uncertainty.
is that rational inattention is conductive to higher-order uncertainty and, in this sense, one can interpret the considered friction as the product of a certain form of “bounded rationality.”

**Uncertainty about fundamentals vs uncertainty about outcomes.** Throughout, we have imposed that $\Theta_T$ becomes commonly known at $T$ in order to clarify that our results do not require lack of common knowledge of concurrent fundamentals. That said, the lessons we have developed are robust to relaxing this assumption, which means replacing $\Theta_t$ with $E_{i,t} [\Theta_t]$ in condition (10). Most importantly, our lessons are robust to replacing $\Theta_t$ with $\theta_{i,t} = \Theta_t + v_{i,t}$, where $v_{i,t}$ is i.i.d. across agents, and let each agent $i$ know at $t = 0$ the entire path of $\theta_{i,t}$, provided that we maintain lack of common knowledge of $\Theta_T$. This clarifies that, for our purposes, the essential friction is that agents lack common knowledge of the fundamentals that move the decisions of others, not that they lack private knowledge of the fundamentals that move their own decisions.

**Higher-order beliefs and rational expectations.** Throughout, we have invited the analyst (the theorist, the econometrician, or the policy maker) to pay close attention to the structure of higher-order beliefs in forward-looking models. This, however, does not mean that the agents inside the model (the consumers or the firms) must also engage in higher-order reasoning. Following the tradition of Muth and Lucas, we instead think of the consumers and the firms in the real world as non-strategic agents, who treat all the macroeconomic outcomes as exogenous stochastic processes and use a “statistical model” when trying to forecast these variables. By requiring that this model is consistent with actual behavior, the rational expectations hypothesis imposes a joint restriction on exogenous impulses, expectations, and outcomes. From this perspective, the exercise conducted in this section, and throughout our paper, is to revisit these restrictions when the auxiliary assumption that the exogenous impulses are common knowledge is relaxed.

### 6 Revisiting Forward Guidance

The preceding section dealt with an abstract dynamic beauty contest. This helped deliver the broader insights of the paper in a sharp and transparent manner. We now return to the application of interest, the New-Keynesian model, and study the implications of our insights for the effectiveness of forward guidance.\(^{29}\)

The following lesson follows directly the previous section. Suppose either that the monetary authority commits on implementing a specific path for the real interest rate, or that prices are infinitely rigid ($\theta = 1$) so that inflation is identically zero and the real interest rate coincides with the nominal one. In either case, we can understand the response of the economy to news about future rates by inspecting the demand block alone. Under complete information, we know, by iterating the familiar Euler condition, that the slope of $y_0$ with respect to $-E_0 [r_T]$ is given by $\sigma$, the elasticity of intertemporal substitution, regardless of $T$. By

---

\(^{29}\)Campbell et al. (2012) distinguish two types of forward guidance, “Delphic” and “Odyssian”, depending on whether the central bank communication is interpreted mostly as a signal of the underlying state of the economy or of the intention of the policy maker to deviate from the policy that will be (ex post) optimal in the future in order to stimulate the economy right now. Through our analysis, we are concerned with the second kind of forward guidance.
contrast, the results of the previous section imply that, as long as information is incomplete, the relevant slope is bounded from above by $\sigma$ and is decreasing in $T$. In this sense, the absence of common knowledge reduces the control that monetary policy has on aggregate demand even if we take for granted her control over the path of the real interest rate. What is more, this reduction is larger the longer the horizon at which the monetary authority commits to change the real interest rate. The reason is that the absence of common knowledge anchors the expectations that consumers form about aggregate spending, thus also attenuating the income multiplier that runs inside the demand block.

The obvious limitation of this lesson is that it treats the path of the real interest rate as the exogenous impulse or, equivalently, that it shuts down inflation. While this is useful for understanding how monetary policy controls aggregate demand holding constant inflation expectations, it is inappropriate for understanding how forward guidance matters during a liquidity trap. In that context, it is essential to treat the real interest rate as endogenous and to capture the feedback loop between aggregate spending and inflation.\(^{30}\)

As noted before, this feedback loop is a GE mechanism that runs between the two blocks of the model. This means that the preceding analysis, which effectively dealt with each block in isolation, is not directly applicable. To understand what the complication is and how it can be addressed, let us momentarily assume that information is complete among the firms even though it is incomplete among the consumers. In this special case, the NKPC is still valid, implying that inflation can be expressed as the present value of future real marginal costs and, thereby, of future consumer spending. Using this fact to substitute away inflation from condition (5), we arrive at the following representation of the equilibrium.

**Lemma 4** When the firms have complete information, equilibrium income (also, consumption) satisfies the following condition at every $t$:

$$y_t = -\sigma R_t - \sigma \sum_{k=1}^{\infty} \beta^k E_t^c[R_{t+k}] + \sum_{k=1}^{\infty} (1 - \beta + k\sigma\kappa) \beta^{k-1} E_t^c[y_{t+k}].$$

This can, once again, be understood as a beauty contest among the consumers. But unlike the one seen earlier in condition (5), the one obtained here subsumes the feedback loop between inflation and spending. This in turn explains why the expectations of income show up with different weights that in condition (5). As a result, the beauty contest seen above is not nested in the abstract analysis of the previous section.

Yet, it is possible to show that all the lessons of Section 5 extend to the new type of beauty contest seen above. In particular, Lemmas 2 and Theorem 2 continue to hold, even though the exact structure of the $\chi$ weights that appear in these results is now different.\(^{31}\) Note next that Lemma 3, which regards the structure in higher-order beliefs, is of course invariant to the best-response structure. It follows that Theorem 1 and all the other results of Section 5 can be directly applied to the question of interest; all we have to do is to interpret the nominal interest rate $T$ periods ahead as the fundamental $\Theta_T$ in the context of Section 5.

---

\(^{30}\)Accordingly, for the rest of the analysis, we let $\theta < 1$ (equivalently, $\kappa > 0$).

\(^{31}\)This was proved in an earlier draft (Angeletos and Lian, 2016a) and is omitted from the present one to economize on space.
To make things a bit more concrete, and to accommodate the possibility that the firms, too, have incomplete information, we henceforth impose the following restriction on monetary policy.

**Assumption 2 (Monetary Policy)** There exists a known $T \geq 2$ such that:

(i) At any $t < T$, the nominal interest rate is pegged at zero, namely $R_t = -\rho$. (Remember $R_t$ is the log-deviation from steady state.)

(ii) At any $t > T$, monetary policy replicates flexible-price outcomes.

(iii) The period-$T$ nominal rate is such that

$$R_T = z + \eta,$$

where $z$ and $\eta$ are random variables, independent of one another and of any other shock in the economy, with $z \sim N(0, \sigma_z^2)$ and $\eta \sim N(0, \sigma_\eta^2)$. The former is realized at $t = 0$; the latter is realized at $t = T$ and is unpredictable prior to that point.

This assumption permits us to interpret $T-1$ as the length of the liquidity trap and $T$ as the horizon over which forward guidance operates. In particular, part (i) is directly motivated by the idea that ZLB constraint is binding during a liquidity trap. Part (ii), on the other hand, permits us to concentrate on expectations of $R_T$, the nominal interest rate that the monetary authority will implement just in the first period after the ZLB has ceased to bind. Finally, part (iii) splits the randomness of $R_T$ into two orthogonal components, along the lines of the example considered in the end of the last section. The first component, $z$, can be interpreted as the period-0 “news” about the period-$t$ interest; such news could be the product of a policy announcement. The second component, $\eta$, captures the residual uncertainty, which is resolved at $t = T$.

We next specify the information structure as follows.

**Assumption 3 (Information)** (i) At $t = 0$, each agent $i$, be it a consumer or a firm, observes a private signal of $z$, given by

$$\omega_i = z + \epsilon_i,$$

where $\epsilon_i$ is an idiosyncratic noise, Normally distributed, with mean zero and variance $\sigma_\epsilon^2 \geq 0$ or $\sigma_f^2 \geq 0$, depending on whether the agent is, respectively, a consumer or a firm.

(ii) No other exogenous information arrives till $t = T$, at which point $R_T$ becomes commonly knowledge.

(iii) The volatilities of the markup and idiosyncratic shocks are arbitrarily large relative to that of $z$.

Part (i) lets each agent’s observation of $z$ to be contaminated by idiosyncratic noise (which, as noted already, could be interpreted as the product of rational inattention). Part (ii), on the other hand, shuts down any exogenous learning. Finally, part (iii) shuts down the endogenous learning that obtains through the observation of the realized market outcomes (wages, prices, etc) in every period. As in the previous
section, these assumptions are not strictly needed, but facilitate a sharp characterization of the incomplete-information equilibrium.\footnote{The last assumption can also be motivated on empirical grounds. In the US data, the estimated contribution of interest-rate shocks to the business-cycle volatility of real output, the price level, and inflation is quite small, whether in the context of SVARs or in the context of estimated DSGE models. It follows that, even the consumers and firms are attentive to macroeconomic statistics, the latter are very imprecise signals of the relevant fundamentals.}

Similarly to the example studied in Section 5, we have that that the hierarchy of beliefs has a simple exponential structure. In particular, the higher-order beliefs of, respectively, the consumers and the firms satisfy, for all \( h \geq 2 \),

\[
\tilde{E}_0^{c,h}[R_T] = \lambda_c^{h-1} \cdot \tilde{E}_0^{c}[R_T] \quad \text{and} \quad \tilde{E}_0^{f,h}[R_T] = \lambda_f^{h-1} \cdot \tilde{E}_0^{f}[R_T],
\]

where

\[
\lambda_c \equiv \frac{\sigma_c^{-2}}{\sigma_c^{-2} + \sigma_z^{-2}} \in (0, 1) \quad \text{and} \quad \lambda_f \equiv \frac{\sigma_f^{-2}}{\sigma_f^{-2} + \sigma_z^{-2}} \in (0, 1),
\]

Note that \( \lambda_c \) and \( \lambda_f \) control how much higher-order beliefs co-move with first-order beliefs; they therefore parameterize the friction of interest. The frictionless, complete-information, benchmark is nested with \( \lambda_c = \lambda_f = 1 \), and a larger friction corresponds to lower values for the \( \lambda \)'s.\footnote{Note that the mean squared error in the typical agent's forecasts of \( R_T \) depends on \( \sigma_z \), whereas the \( \lambda_c \) and \( \lambda_f \) do not. It follows that we can vary the quality of these forecasts are without varying \( \lambda_c \) and \( \lambda_f \), which in turn justifies why it is best to think of the \( \lambda_c \) and \( \lambda_f \) as parameters that govern the degree of common knowledge as opposed to the precision of the information about the future policy. In this sense, we have also disentangled the issue of how accurate or credible the news are from the issue of how large the departure from common knowledge is.}

**Proposition 5 (Forward Guidance with CK)** Suppose \( \lambda_c = \lambda_f = 1 \), which means that the news, \( z \), is common knowledge among both the consumers and the firms. There exists a scalar \( \phi_T^* \geq \sigma \) such that, for all realizations of uncertainty,

\[
y_0 = y_0^{trap} - \phi_T^* E_0[R_T]. \tag{24}
\]

where \( y_0^{trap} \) is the “liquidity trap” level of output (i.e., the one obtained when the period-\( T \) nominal interest rate is fixed at the steady-state value). Furthermore, \( \phi_T^* \) is strictly increasing in \( T \) and diverges to infinity as \( T \to \infty \).

This result contains the predictions of the textbook New-Keynesian model regarding the power of forward guidance during a liquidity trap: this power, as measured by \( \phi_T^* \), is predicted to increase without bound as the time of action is pushed further and further into the future. It is this prediction, along with its quantitative evaluation, that constitutes the so-called “forward guidance puzzle”(Carlstrom, Fuerst and Paustian, 2012; Del Negro, Giannoni and Patterson, 2012; McKay, Nakamura and Steinsson, 2016b).

Contrast this prediction with the PE effect of future interest rates: as noted earlier, the PE effect is decreasing in \( T \), simply because of the discounting that is embedded in intertemporal preferences. The reason that \( \phi_T^* \) exhibits the opposite pattern is because of the GE effects that run within and between the two blocks of the model. In particular, the income multiplier implies that \( \phi_T^* \) would stay constant with \( T \) even if we
were to shut down the inflation response. The feedback loop between aggregate spending and inflation then explains why $\phi_T^*$ actually increases with $T$.

Let us explain. Reducing the interest rate at $t = T$ increases spending and causes inflation at $t = T$. Because the nominal interest rate is pegged prior to $T$, this translates to a low real interest rate between $T - 1$ and $T$. This stimulates demand at $T - 1$, contributing to even higher inflation at $T - 1$, which feeds to even higher demand at $T - 2$, and so on. A longer horizon therefore maps to a larger the number of iterations in this feedback loop and, thereby, to a stronger cumulative effect at $t = 0$. Finally, as $T \to \infty$, this feedback loop explodes, which explains why $\phi_T^*$ increases without bound.

It is worth noting that the scalar $\phi_T^*$ is invariant to the ratio $\sigma_z/\sigma_\eta$, which parameterizes the precision of the available news: varying the ratio $\sigma_z/\sigma_\eta$ affects how much $E_0[R_T]$ varies with $R_T$, but does not affect how much either $y_0$ or $\pi_0$ vary with $E_0[R_T]$. This property extends to the incomplete-information scenario studied next and explains the sense in which both the puzzle and the resolution we offer are orthogonal to the question of how accurate or credible the news about the future interest rates might be.

**Proposition 6 (Forward Guidance without CK)** Suppose that $\lambda_c < 1$ and/or that $\lambda_f < 1$, which means that at least one group of agents lacks common knowledge of the news. There exists a scalar $\phi_T$ such that, for all realizations of uncertainty,

$$y_0 = y_0^{trap} - \phi_T \cdot E_0^c[R_T].$$

Furthermore, the following properties hold:

(i) $\phi_T$ is bounded between the PE effect and the complete-information counterpart: $\sigma_\beta^T < \phi_T < \phi_T^*$.

(ii) $\phi_T$ is strictly in both $\lambda_c$ and $\lambda_f$; the ratio $\phi_T/\phi_T^*$ is strictly decreasing in $T$ and converges to 0 as $T \to \infty$; finally, when $\lambda_c$ is sufficiently low, $\phi_T$ also converges to 0 as $T \to \infty$.

Part (i) formalizes the sense in which the standard model “maximizes” or “overstates” the power of forward guidance: $\phi_T^*$ is an upper bound to the prediction that the analyst can make if she maintains the rational-expectations hypothesis but removes common knowledge of the policy news. By varying the degree of common knowledge, we effectively span the range between this upper bound and the underlying PE effect.

Part (ii) is a version of our earlier “horizon effect”: by attenuating the feedback loop between inflation and spending, as well as the GE effects that run within each block of the model, lack of common knowledge reduces the power of forward guidance by a factor that increases with $T$. This attenuation increases without bound in the sense that $\phi_T$ becomes vanishingly small relative to $\phi_T^*$ as $T \to \infty$. Finally, if the friction is large enough (i.e., if $\lambda_c$ is small enough), this effect can be strong enough that $\phi_T$ is decreasing in $T$, not only relative to $\phi_T^*$, but also in absolute value.

**A numerical illustration.** We now use a numerical example to illustrate our findings. We interpret the period length as a quarter and adopt the calibration of the textbook New-Keynesian model found in Galí

---

$^{34}$As noted before, this is readily seen by iterating on the Euler condition of the representative consumer.
(2008). That is, we set the discount factor to 0.99, the Frisch elasticity to 1, the elasticity of intertemporal substitution to 1, and the price revision rate to $1/3$.

What remains is to pick the values of $\lambda_c$ and $\lambda_f$, that is, the departure from common knowledge. The existing literature offers little guidance on how to make this choice. In want of a better alternative, we let $\lambda_c = \lambda_f = 0.75$ and interpret this as a situation in which every agent who has heard the policy announcement believes that any other agent has failed to hear, or “trust”, the announcement with a probability equal to 25%. This is arguably a modest “grain of doubt” in the minds of people about their ability to coordinate the adjustment in their beliefs and their behavior.

The solid red line in Figure 1 plots the resulting attenuation effect, as measured by the ratio $\phi_T/\phi_T^*$, against the horizon length, $T$. By setting $\lambda_c = \lambda_f$, this line assumes that the consumers and the firms are subject to the same informational friction. The dashed blue line isolates the friction in the consumer side ($\lambda_c = 0.75$) by shutting it down in the firm side ($\lambda_f = 1$). The dotted black line does the converse.

Not surprisingly, the attenuation is strongest when the friction is present in both sides. More interestingly, the effect is quantitatively significant. For example, at a horizon of 5 years ($T = 20$), the power of forward guidance is only one tenth of its common-knowledge counterpart. This is on top of any mechanical effect that the noise may have on the size of the shift of the expectations of future interest rates: by construction, the documented attenuation effect is normalized by the size of the variation in the first-order beliefs of $R_T$.\footnote{Although Coibion and Gorodnichenko (2012) provide evidence in support of the kind of informational friction we have accommodated here, that evidence does not regard the context of forward guidance. Yet, taking that evidence at face value could justify an even larger departure from common knowledge: whenever a shock hits the economy, the average forecast error in the expectations of inflation appears to be half as large as the actual response in inflation, which translates to a value for $\lambda$ close to 0.5.}

One can, of course, quibble about the appropriate parameterization. For instance, estimated DSGE models typically assume a higher degree of price stickiness than the one assumed here. This tends to reduce the attenuation effect. For instance, raising the value of $\theta$ from $2/3$, the value in Gali (2008), to 0.85, the value in Christiano, Eichenbaum and Rebelo (2011), implies that the ratio $\phi_T/\phi_T^*$ increases from about 0.1 to about 0.3 at $T = 20$. That said, note that menu-cost models calibrated to micro data indicate that the “right” value for $\theta$ is probably even smaller than $2/3$. In any event, our goal here is only to illustrate; a more comprehensive

Figure 1: Attenuation effect, relative to common-knowledge benchmark, at different horizons.
This illustrates the following broader point: by anchoring the movements in the expectations of economic outcomes relative to the movements in the expectations of the policy instrument, our paper helps operationalize the idea that policy makers may have harder time managing the former kind of expectations than the latter. This helps may explain, for example, why forward guidance may trigger a large movement in the term structure without a commensurate movement in expectations of inflation and income.

In Appendix C, we elaborate on the mechanics behind Figure 1. We first show how the the effects of the considered friction can be understood through the lenses of a discounted Euler condition and a discounted NKPC; this is, in effect, an application of our earlier, more abstract, result in Proposition 4. This representation helps connect our paper to McKay, Nakamura and Steinsson (2016b, a) and Gabaix (2016). It also helps explains why almost all of the effect seen in Figure 1 comes from the attenuation of two GE mechanisms: the one that runs within the supply block of the model (the dependence of current inflation to future inflation); and the one that runs between the two blocks (the feedback loop between inflation and spending). By contrast, the attenuation of the income multiplier play a negligible role.

Intuitively, this is because, in the textbook version of the New-Keynesian model, which we have employed here, consumers have infinite horizons and their spending depends on expectations of output only through the present value of permanent income. This means that varying the expectations of income in the next, say, 5 years has a minuscule effect on current spending. It follows that the attenuation of this particular GE mechanism (the income multiplier) is also quantitatively insignificant. Allowing for short horizons, precautionary motives, and feedback effects between housing prices and consumer spending is likely to increase the quantitative importance of this mechanism and, in so doing, also increase the relative importance of anchoring the consumers’ expectations of income. This indicates the likely value of extending our analysis to more realistic versions of the demand block of the New-Keynesian model, such as those studied in McKay, Nakamura and Steinsson (2016b), Auclert (2017), and Kaplan, Moll and Violante (2016).

Having said that, it is worth emphasizing the following point. While these papers are concerned exclusively with the demand block of the New-Keynesian model, our paper revisits both blocks at once. This seems important given that (i) the NKPC is the key equation that distinguishes the New-Keynesian model from its RBC counterparts; (ii) many challenges faced by the New-Keynesian model are tied to the poor empirical performance of the NKPC; and (iii) our approach helps explain why inflation may move little in response to news about future demand and marginal costs. Complementary in this regard is Wiederholt (2015), which also emphasizes the importance of anchoring inflation expectations.

7 Revisiting Fiscal Multipliers

To study the implications of our analysis for fiscal policy, we introduce government spending in the model. In line with our earlier analysis, we then focus on the question of how current aggregate income responds to “news” about future government spending at different horizons. As usual, we treat the level of gov-
ernment spending as exogenous and assume that its is financed with lump-sum taxation. But unlike the standard practice, we remove common knowledge of the future level of government spending and of its macroeconomic effects.

The beauty-contest representation of the economy in conditions (5) and (6) still holds, modulo the following adjustment: the real marginal cost is now given by \( mc_t = \Omega_c c_t + (1 - \Omega_c) g_t \), where \( g_t \) the level of government spending and \( \Omega_c \in (0, 1) \) is a constant that increases with the steady-state fraction of GDP that is absorbed by private consumption. Note then that government spending enters the equilibrium dynamics of inflation and consumer spending only insofar as the real marginal cost increases with the level of output and, thereby, with the level of government spending.

Pick now any pair \((T, T')\) such that \(2 \leq T \leq T'\). We want \(T'\) to capture the length of the liquidity trap and \(T\) the period during which a fiscal stimulus is going to be enacted. Accordingly, we let monetary policy satisfy Assumption 2, with \(T\) replaced by \(T'\). We also fix \(R_{T'} = 0\), so as to focus on fiscal policy. Finally, similar as Assumption 2, we assume that \(g_t = 0\) for all \(t \neq T\) and so as to focus on beliefs about the level of government spending at horizon \(T\), \(g_T\). Under an information structure similar as Assumption 3, we can then show the following.

**Proposition 7** Propositions 5 and 6 hold with \(\phi_T T\) and \(\phi_T T\) reinterpreted as, respectively, the complete- and the incomplete-information slope of \(y_0\) with respect to \(\tilde{E}_0[g_T]\).

The part of this result that regards \(\phi_T T\) is the analogue of Proposition 5: under common knowledge, the current impact of a fiscal stimulus of a given size increases as the stimulus is pushed further into the future. This is a fiscal-policy variant of the forward guidance puzzle. The underlying logic is essentially the same: the PE effect of a fiscal stimulus, which is its direct effect on the concurrent real marginal costs, decays with the horizon \(T\), but the GE effects that run within and between the two blocks of the model overturn this property. The other part of the result, which regards \(\phi_T T\), is the analogue of Proposition 6: once we relax the assumption that there is common knowledge of the size and the consequences of the fiscal stimulus, the “fiscal multiplier” is reduced at every \(T\), and the more so the larger \(T\) is.

In short, while the standard model predicts that fiscal stimuli must be back-loaded in order to “pile up” the feedback effects between aggregate spending and inflation, our approach offers a rationale for front-loading them. Such front-loading reduces the “coordination friction” in the economy: the sooner the fiscal stimulus is enacted, the less concerned the agents have to be about the beliefs and the responses of others at long horizons, and, thereby, the easier it is to coordinate on a large response today.\(^{37,38,39}\)

\(^{37}\)Similarly to Christiano, Eichenbaum and Rebelo (2011), Woodford (2011), and Werning (2012), the fiscal multipliers we have been concerned with are those that obtain when the ZLB constraint binds. The investigation of how our insights extend when the economy is away from this constraint and monetary policy a Taylor rule or replicates flexible prices, is the subject of ongoing work.

\(^{38}\)Of course, whether the provided rationale for front-loading is sufficiently strong to offset the standard back-loading property depends on the severity of the informational friction and all the parameters that govern the magnitude of the GE feedback loops, such as the value of \(\kappa\). Letting \(\kappa\) be small enough guarantees that the incomplete-information fiscal multiplier decreases with \(T\), not only relative to its complete-information counterpart, but also in absolute value.

\(^{39}\)One can enrich the channels through which fiscal policy matters by adding financial frictions and “hand-to-mouth consumers” (Galí, López-Salido and Vallés, 2007; Kaplan, Moll and Violante, 2016). But even in these settings, fiscal multipliers are driven, in
8 Conclusion

Modern macroeconomics assigns a crucial role to forward-looking expectations, such as consumer expectations of future income and future real interest rates or firm expectations of future inflation and future real marginal costs. This property seems desirable and realistic. However, by assuming common knowledge along with rational expectations, the dominant modeling practice hardwires a certain kind of perfection in the ability of economic agents to understand what’s going on around them, to align their beliefs, and to coordinate their responses to any exogenous impulse. In so doing, it also maximizes the general-equilibrium multipliers on fiscal and monetary policies.

Conversely, allowing for higher-order uncertainty helps accommodate a realistic friction in the ability of economic agents to forecast, or comprehend, the macroeconomic effects of policy news. This in turn arrests the underlying general-equilibrium feedback loops and reduces the ability of policy makers to steer the economy, especially when the policy news regard longer horizons.

We first formalized these ideas within a context of an abstract beauty contest game, which was flexible enough to nest either the demand or the supply block of the New-Keynesian model, as well as other applications. We next showed how these ideas lessen the forward guidance puzzle and offer a rationale for front-loading fiscal stimuli.40

By anchoring the movements in the expectations of economic outcomes relative to the movements in the expectations of the policy instrument, our paper helps operationalize the idea that policy makers may have harder time managing the former kind of expectations than the latter. But it also hints to the following possibility: especially when it comes to longer horizons, it may be more important for the policy maker to communicate her intended path for the economy (e.g., for output and inflation) than her intended path for the policy instrument. What is more, these communications must be “loud and clear, not only in the ears of “Wall Street” (financial markets), but also in the ears of “Main Street” (firms and consumers). We leave the exploration of these ideas open for future research.

Another venue for future research is the investigation of the implications of our insights for the equilibrium-determinacy issues and the “neo-Fisherian” effects discussed in, inter alia, Cochrane (2016a,b) and Garcia-Schmidt and Woodford (2015): these issues hinge on the same general-equilibrium feedback loops and higher-order beliefs as the one we have been concerned with in this paper.

A third possibility is the extension of our analysis to settings with financial frictions. Such frictions can give rise to feedback loops between asset prices and economic activity, such as those studied in Kiyotaki and Moore (1997) and Brunnermeier and Sannikov (2014). Under the lenses of our analysis, the extent to which the underlying shocks, or the news about future fundamentals, are common knowledge emerge as a crucial determinant of the equilibrium volatility in asset prices and economic activity.

Let us conclude by emphasizing once more the broader meaning of the friction we have sought to accom-
modate in this paper. Higher-order uncertainty can be the by-product either of “noise” in the aggregation of information through markets and other social institutions, or of “bounded rationality” in the form of rational inattention. Either way, higher-order uncertainty helps accommodate a friction in how well the agents can forecast, or comprehend, what others are doing and how aggregate outcomes may respond to exogenous impulses. We believe that this adds realism to macroeconomic theory, while allowing one to remain inside the “comfort zone” of rational expectations.
Appendix A: Proofs

To clarify the difference between the original variables and their log-deviations from steady state, throughout this Appendix we use a tilde over a variable denote the log-deviation of this variable from its steady-state counterpart, and reserve the non-tilde notation for the original variables.

Proof of Proposition 1. We proceed in multiple steps, starting with the behavior of the consumers, proceeding with the behavior of the firms, and concluding with market clearing and with the derivation of the two beauty contests shown in the main text.

Consumers. Let \( \pi_t = \frac{p_t}{p_{t-1}} \) denote the period-\( t \) gross inflation rate. Consider an arbitrary consumer \( i \in I_c \).

As usual, the following intertemporal budget constraint holds in all periods and all states of Nature:

\[
\sum_{k=0}^{+\infty} \left\{ \Pi_{j=1}^{k} \left( \frac{R_{t+j-1}}{\pi_{t+j}} \right)^{-1} c_{i,t+k} \right\} = a_{i,t} + \sum_{k=0}^{+\infty} \left\{ \Pi_{j=1}^{k} \left( \frac{R_{t+j-1}}{\pi_{t+j}} \right)^{-1} \left( w_{i,t+k} n_{i,t+k} + e_{i,t+k} \right) \right\} .
\]

Taking the log-linear approximation of the above around the steady state, we get the following:

\[
\sum_{k=0}^{+\infty} \beta^k \tilde{c}_{i,t+k} = \tilde{a}_{i,t} + \sum_{k=0}^{+\infty} \beta^k \{ \Omega \left( \tilde{w}_{i,t+k} + \tilde{n}_{i,t+k} \right) + (1 - \Omega) \tilde{e}_{i,t+k} \} ,
\]

where \( \Omega \) is the ratio of labor income to total income in steady state. The consumer’s optimality conditions, on the other hand, can be expressed as follows:

\[
\tilde{n}_{i,t} = \frac{1}{\epsilon} \left( \tilde{w}_{i,t} - \tilde{c}_{i,t} \right) ,
\]

\[
\tilde{c}_{i,t} = \left[ \tilde{e}_{i,t+1} - \tilde{R}_{t} + \tilde{\pi}_{t+1} \right] = E_{i,t} [\tilde{e}_{i,t+1} - \tilde{\pi}_{t+1}] ,
\]

where \( E_{i,t} [\cdot] \) is the expectation of consumer \( i \) in period \( t \). The first condition describes optimal labor supply; the second is the individual-level Euler condition, which describes optimal consumption and saving.

At this point, it is worth emphasizing that our analysis preserves the standard Euler condition at the individual level. This contrasts with McKay, Nakamura and Steinsson (2016a,b) and Werning (2015), where liquidity constraints cause this condition to be violated for some agents, as well as with Gabaix (2016), where a cognitive friction causes this condition to be violated for every agent. We revisit this point in Appendix C, when we show that our analysis rationalizes a discounted Euler condition at the aggregate level, in spite of the preservation of the standard condition at the individual level.

Combining conditions (27), (28) and (29), we obtain the optimal expenditure of consumer \( i \) in period \( t

---

\(^{41}\)One should think of the state of Nature as a realization the exogenous payoff relevant shocks along with the cross-sectional distribution of the exogenous signals (information) received by the agents.

\(^{42}\)In a symmetric steady state, \( a_{i,t} = a^* = 0 \). For this reason, we let \( a_{i,t} \equiv \frac{a_{i,t}}{c^*} \), where \( c^* \) is steady-state consumption.
as a function of the current and the expected future values of wages, dividends, and real interest rates:

\[
\tilde{c}_{i,t} = \frac{\epsilon(1-\beta)}{\epsilon+1} \tilde{a}_{i,t} - \sum_{k=1}^{+\infty} \beta^k (E_{i,t} [\tilde{r}_{t+k}]) + (1-\beta) \sum_{k=1}^{+\infty} \beta^k E_{i,t} \left[ \frac{(1+\Omega)}{\epsilon+1} \tilde{w}_{i,t+k} + \frac{(1-\Omega)}{\epsilon+1} \tilde{e}_{i,t+k} \right],
\]

This condition, which is a variant of the consumption function seen in textbook treatments of the Permanent Income Hypothesis,\(^{43}\) contains two elementary insights. First, all future variables—wages, dividends, and real interest rates—are discounted. Second, the current spending of a consumer depends on the present value of her income, which in turn depends, in equilibrium, on the future spending of other consumers.

The first property guarantees that the decision-theoretic, or partial-equilibrium, effect of forward guidance diminishes with the horizon at which interest rates are changed; the second represents a dynamic strategic complementarity, which is the modern reincarnation what was known as the “income multiplier” in the IS-LM framework. We elaborate on these two points in the sequel. For the time being, we aggregate condition (30), and use the facts that assets average to zero and that future idiosyncratic shocks are unpredictable, to obtain the following condition for aggregate spending:

\[
\bar{c}_t = -\sum_{k=1}^{+\infty} \beta^k \bar{E}^c_t [\tilde{r}_{t+k}] + (1-\beta) \left[ \frac{(1+\Omega)}{\epsilon+1} \bar{w}_t + \frac{(1-\Omega)}{\epsilon+1} \bar{e}_t \right] + (1-\beta) \sum_{k=1}^{+\infty} \beta^k \bar{E}^c_t \left[ \frac{(1+\Omega)}{\epsilon+1} \bar{w}_{t+k} + \frac{(1-\Omega)}{\epsilon+1} \bar{e}_{t+k} \right],
\]

where \(\bar{E}^c_t [\cdot]\) henceforth denotes the average expectation of the consumers in period \(t\).

**Firms.** Consider a firm \(j \in I_f\) that gets the chance to reset its price during period \(t\). The optimal reset price, denoted by \(\tilde{p}^j_t\), is given by the following:

\[
\tilde{p}^j_t = (1-\beta \theta) \left\{ (\tilde{m}c^j_t + \tilde{p}_t) + \sum_{k=1}^{+\infty} (\beta \theta)^k E^j_{j,t} \left[ \tilde{m}c^j_{t+k} + \tilde{p}_{t+k} \right] \right\} + (1-\beta \theta) \tilde{p}^j_t,
\]

where \(E^j_{j,t} [\cdot]\) denotes the firm’s expectations in period \(t\), \(\tilde{m}c^j_t = \bar{w}^j_t\) is its real marginal cost in period \(t\), and \(\tilde{p}^j_t\) is the corresponding markup shock. The interpretation of this condition is familiar: the optimal “reset” price is given by the expected nominal marginal cost over the expected lifespan of the new price, plus the markup. Aggregating the above condition, using the fact that the past price level is known and that inflation is given by \(\bar{\pi}_t = (1-\theta) (\tilde{p}^j_t - \tilde{p}_{t-1})\), where \(\tilde{p}^j_t \equiv \int_{I_f} \tilde{p}^j_t \, dj\), we obtain the following condition for the level of

\(^{43}\)To see this more clearly, suppose that initial assets are zero, that the real interest rate is expected to equal the discount rate at all periods, and that labor supply is fixed (\(\epsilon \to \infty\)). Condition (30) then reduces to \(\bar{e}_{t,t} = (1-\beta) [\Omega \bar{w}_{i,t} + (1-\Omega) \bar{e}_{i,t}] + (1-\beta) \sum_{k=1}^{+\infty} \beta^k E_{i,t} \left[ \Omega \bar{w}_{i,t+k} + (1-\Omega) \bar{e}_{i,t+k} \right]\), which means that optimal consumption equals “permanent income” (the annuity value of current and future income). Relative to this benchmark, condition (30) adjusts for three factors: for the endogeneity of labor supply, which explains the different weights on wages and dividends; for initial assets, which explains the first term in condition (30); and for the potential gap between the real interest rate and the subjective discount rate, which explains the second term.
inflation in period $t$:\footnote{To economize notation, when we transit from (32) to (33), we rescale the markup shock: the $\tilde{\mu}_t$ that appears in (6) equals $\tilde{\mu}_t / \left(1 + \epsilon \right)$ times the original $\mu_t$.}

$$\tilde{\pi}_t = \frac{(1-\theta)(1-\beta \theta)}{\theta} \tilde{m}c_t + \frac{(1-\theta)(1-\beta \theta)}{\theta} \sum_{k=1}^{+\infty} (\beta \theta)^k \bar{E}_t^f [\tilde{m}c_{t+k}] + \frac{1-\theta}{\theta} \sum_{k=1}^{+\infty} (\beta \theta)^k \bar{E}_t^f [\tilde{\pi}_{t+k}] + \tilde{\mu}_t,$$  \hspace{1cm} (33)

where $\bar{E}_t^f [\cdot]$ henceforth denotes the average expectation of the firms. The latter may or may not be the same as the average expectation of the consumers.

**Market Clearing, Wages, and Profits.** Because the final-good sector is competitive and the technology satisfies (4) and (3), we have that $\tilde{p}_t = \int_{I_f} \tilde{p}_t^j dj$ and $\tilde{y}_t = \int_{I_f} \tilde{y}_t^j dj = \int_{I_f} \tilde{p}_t^j dj$. The latter, together with market clearing in the labor market, gives $\tilde{y}_t = \tilde{\eta}_t = \int_{I_f} \tilde{\eta}_i, di$. Market clearing in the market for the final good, on the other hand, gives

$$\tilde{y}_t = \tilde{c}_t \equiv \int_{I_f} \tilde{c}_{i,t} di.$$  

Finally, note that the real profit of monopolist $j$ at period $t$ is given by $c_t^j = \left( \frac{\tilde{p}_t^j}{\tilde{w}_t^j} - w_t^j \right) \tilde{y}_t$. Log-linearizing and aggregating the latter gives $\tilde{c}_t = -\frac{\Omega}{1 - \Omega} \tilde{w}_t + \tilde{y}_t$. Combining all these facts with (28), the optimality condition for labor supply, we arrive at the following characterization of the aggregate wages and the profits:

$$\tilde{w}_t = \tilde{m}c_t = (\epsilon + 1) \tilde{y}_t, \quad \tilde{c}_t = \left[ 1 - \frac{\Omega(\epsilon + 1)}{\epsilon + \Omega} \right] \tilde{y}_t, \quad \text{and} \quad \frac{(\epsilon + 1)\Omega}{\epsilon + \Omega} \tilde{w}_t + \frac{\epsilon(1-\Omega)}{\epsilon + \Omega} \tilde{c}_t = \tilde{y}_t.$$  \hspace{1cm} (34)

**Beauty Contests.** Condition (31), which follows merely from consumer optimality, pins down aggregate spending as a function of the average beliefs of wages, profits, interest rates, and inflation. As we impose REE, a consumer can infer that (34) holds, aggregate spending can then be expressed as a function of the consumers’ average beliefs of interest rates, of inflation, and of aggregate spending itself. This is condition (5), the consumption beauty contest. Similarly, combining (33) and (34), we can express aggregate inflation as a function of the firms’ average beliefs of aggregate spending and of inflation itself. This is condition (6), the inflation beauty contest.

This complete the proof of Proposition 1.

**Proof of Proposition 2.** Because $\Theta_t$ is zero for all $t > T$, $a_t$ is also zero for all $t > T$.\footnote{As mentioned in main text, we assumelim_{k\to\infty} \gamma^k E_{t+k} [a_{t+k}] = 0 and rule out “extrinsic bubbles.”} Using this fact along with the fact that $\Theta_t$ is zero also for $t < T$, and iterating on condition (11), we can obtain $a_t$ for all $t < T$ as a linear function of the average first- and higher-order beliefs about $\Theta_T$; see, e.g., Lemma 1 below for an explicit characterization in the the case without learning. When information is complete, all agents share the same first-order beliefs about $\Theta_T$ with probability one, and this fact is itself common knowledge. It follows that higher-order beliefs collapse to first-order beliefs and, therefore, $a_t$ becomes a linear function of $E_t[\Theta_T]$, the commonly shared expectation of $\Theta_T$. Now take any $t < \tau \leq T$ and any pair of agents $i,j$. Complete information guarantees that $E_t[\Theta_T] = E_t[\Theta_T] = E_{\tau} E_t[\Theta_T]$ with probability one. And
since we already argued that, in equilibrium, $a_t$ is a known linear function of $E_T[\Theta_T]$, it is also the case $E_{i,t}[a_T] = E_{j,t}[a_T]$. That is, complete information (in the sense of Definition 1) rules out imperfect consensus (in the sense of Definition 2).

\textbf{Proof of Lemma 1.} Lemma 1 follows directly from the argument in main text.

\textbf{Proof of Lemma 2.} We prove the following stronger result: there exists positively-valued coefficients \{\chi_{h,k}\}_{k \geq 1, 1 \leq h \leq k}, such that, for any $t \leq T - 1$,

$$a_t = \sum_{h=1}^{T-t} \chi_{h,T-t} \bar{E}_t^h \left[ \Theta_T \right],$$

(35)

where each $\chi_{h,k}$ is a function of $(\alpha, \gamma)$ and $\bar{E}_t^h$ is defined recursively by $\bar{E}_1^h = \bar{E}_1$ and $\bar{E}_t^h = \bar{E}_t \left[ \bar{E}_{t}^{h-1} \right]$ for every $h \geq 2$. We now prove this claim by induction. First, consider $t = T - 1$. From $a_T = \Theta_T$ and condition (15), we have $a_{T-1} = (\gamma + \alpha) \bar{E}_{T-1} \left[ \Theta_T \right]$. It follows that condition (35) holds for $\chi_{1,1} = \gamma + \alpha$.

Now, pick an arbitrary $t \leq T - 2$, assume that condition (35) holds for all $\tau \in \{t + 1, \ldots, T - 1\}$, and let us prove that it also holds for $t$. From condition (15), we have

$$a_t = \gamma^{T-t-1} (\gamma + \alpha) \bar{E}_t \left[ \Theta_T \right] + \alpha \sum_{k=1}^{T-t-1} \gamma^{k-1} \bar{E}_t \left[ \sum_{h=1}^{T-t-k} \chi_{h,T-t-k} \bar{E}_{t+k}^h \left[ \Theta_T \right] \right]$$

$$= \gamma^{T-t-1} (\gamma + \alpha) \bar{E}_t \left[ \Theta_T \right] + \sum_{h=1}^{T-t} \sum_{k=1}^{T-t-h} \left( \alpha \gamma^{k-1} \chi_{h,T-t-k} \bar{E}_{t+k}^h \left[ \Theta_T \right] \right)$$

(36)

where the second line uses Assumption 1 (no learning). As a result, condition (35) holds for

$$\chi_{1,T-t} = \gamma^{T-t-1} (\gamma + \alpha) \quad \text{and} \quad \chi_{h+1,T-t} = \sum_{k=1}^{T-t-h} \alpha \gamma^{k-1} \chi_{h,T-t-k} \quad h \in \{1, \ldots, T - t - 1\}.$$  

(37)

This finishes the proof.

\textbf{Proof of Lemma 3.} Note that every agent $i$’s information set at period 0 is drawn i.i.d. from the aggregate state of the Nature (for simplicity, we call this property “symmetry” in the rest of this proof), we have, for all

\footnote{As mentioned in main text, we assume $\lim_{k \to \infty} \gamma^k E_{i,t} \left[ a_{t+k} \right] = 0$ and rule out “extrinsic bubbles.” Together with the fact $\Theta_t$ is zero for all $t > T$, $a_t$ is also zero for all $t > T$. As a result, $a_T = \Theta_T$ from condition (11).}

\footnote{To prove Theorem 1, we need Lemma 3 and Theorem 2. As a result, we start from their proves.}
\[ h \geq 2, \]
\[
\text{Cov} \left( E_0^h[\Theta_T], E_0^1[\Theta_T] \right) = \text{Cov} \left( E_{i,0} \left[ E_0^{h-1}[\Theta_T] \right], E_0^1[\Theta_T] \right),
\]
\[
= \text{Cov} \left( E_0^{h-1}[\Theta_T], E_{i,0} \left[ E_0^1[\Theta_T] \right] \right) = \text{Cov} \left( E_0^{h-1}[\Theta_T], E_0^1[\Theta_T] \right),
\]
where the second and the third equality come from the law of iterated expectations. By the same argument, we have, for all \( h \geq 2 \) and \( j \in \{1, 2, \ldots, h-1\} \),
\[
\text{Cov} \left( E_0^h[\Theta_T], E_0^1[\Theta_T] \right) = \text{Cov} \left( E_0^{h-j}[\Theta_T], E_0^{1+j}[\Theta_T] \right). \tag{38}
\]
From the previous condition, for \( k \geq 1 \), we have
\[
\beta_{2k} = \frac{\text{Cov} \left( E_0^k[\Theta_T], E_0^{k+1}[\Theta_T] \right)}{\text{Var} \left( E_0^1[\Theta_T] \right)} = \frac{\text{Cov} \left( E_0^k[\Theta_T], E_{i,0} \left[ E_0^k[\Theta_T] \right] \right)}{\text{Var} \left( E_0^1[\Theta_T] \right)} = \frac{\text{Var} \left( E_{i,0} \left[ E_0^k[\Theta_T] \right] \right)}{\text{Var} \left( E_0^1[\Theta_T] \right)} \geq 0 \quad \forall i, \tag{39}
\]
where the second equation follows from symmetry and the last equation follows from the law of iterated expectations. Similarly, for \( k \geq 1 \), we have
\[
\beta_{2k-1} = \frac{\text{Cov} \left( E_0^k[\Theta_T], E_0^k[\Theta_T] \right)}{\text{Var} \left( E_0^1[\Theta_T] \right)} = \frac{\text{Var} \left( E_0^k[\Theta_T] \right)}{\text{Var} \left( E_0^1[\Theta_T] \right)} \geq 0. \tag{40}
\]
Now, note that for any random variable \( X \), and any information set \( I \), according to law of total variance, we have:
\[
\text{Var} \left( E[X|I] \right) \leq \text{Var} \left( X \right).
\]
As a result, \( \text{Var} \left( E_0^{k+1}[\Theta_T] \right) = \text{Var} \left( E \left[ E_{i,0} \left[ E_0^k[\Theta_T] \right] | s \right] \right) \leq \text{Var} \left( E_{i,0} \left[ E_0^k[\Theta_T] \right] \right) \) and \( \text{Var} \left( E_{i,0} \left[ E_0^k[\Theta_T] \right] \right) = \text{Var} \left( E \left[ E_0^k[\Theta_T] | \omega_i \right] \right) \leq \text{Var} \left( E_0^k[\Theta_T] \right) \), where, as a reminder, \( s \) is the aggregate state of the Nature and \( \omega_i \) is the information set of agent \( i \). Together with conditions (39) and (40), we know that, for all \( k \geq 1 \), \( \beta_{2k+1} \leq \beta_{2k} \leq \beta_{2k-1} \). This proves that, for all \( h \geq 2 \), \( \beta_h \in [0,1] \) and is weakly decreasing in \( h \).
Now we try to prove \( \beta_h \) is strictly decreasing in \( h \). Note that from condition (39), \( \beta_2 = \frac{\text{Var} \left( E_{i,0} \left[ E_0[\Theta_T] \right] \right)}{\text{Var} \left( E_0^1[\Theta_T] \right)} \leq \beta_1 = 1 \). If \( \beta_2 = \beta_1 = 1 \), we have \( \text{Var} \left( E_{i,0} \left[ E_0[\Theta_T] \right] \right) = \text{Var} \left( E_0[\Theta_T] \right) \) for all \( i \). This means that
\[
\text{Var} \left( E_{i,0} \left[ E_0[\Theta_T] \right] - E_0[\Theta_T] \right) = \text{Var} \left( E_{i,0} \left[ E_0[\Theta_T] \right] \right) + \text{Var} \left( E_0[\Theta_T] \right) - 2\text{Cov} \left( E_{i,0} \left[ E_0[\Theta_T] \right] , E_0[\Theta_T] \right) = \text{Var} \left( E_0[\Theta_T] \right) - \text{Var} \left( E_{i,0} \left[ E_0[\Theta_T] \right] \right) = 0, \tag{41}
\]
where the second equality follows from the law of iterated expectations. As a result, for all \( i, E_{i,0} \left[ E_0[\Theta_T] \right] = E_0[\Theta_T] \) almost surely. We henceforth have that
\[
\text{Var} \left( E_0[\Theta_T] \right) = \text{Cov} \left( \Theta_T, E_0^2[\Theta_T] \right) = \text{Cov} \left( \Theta_T, E_{i,0} \left( E_0[\Theta_T] \right) \right) = \text{Cov} \left( \Theta_T, E_0[\Theta_T] \right) = \text{Cov} \left( \Theta_T, E_{i,0} \left[ E_0[\Theta_T] \right] \right) = \text{Var} \left( E_{i,0} \left[ E_0[\Theta_T] \right] \right).
\]
where the first equality follows a similar argument as condition (38), the second and fourth equalities follow from symmetry, the third equality follows from $E_{i,0} \left[ E_0[\Theta_T] \right] = E_0[\Theta_T]$ almost surely, and the last equality follows from the law of iterated expectations. This means that

$$\text{Var} \left( E_{i,0} [\Theta_T] - E_0[\Theta_T] \right) = \text{Var} \left( E_{i,0} [\Theta_T] \right) + \text{Var} \left( E_0[\Theta_T] \right) - \text{Cov} \left( E_{i,0} [\Theta_T], E_0[\Theta_T] \right) = \text{Var} \left( E_{i,0} [\Theta_T] \right) - \text{Var} \left( E_0[\Theta_T] \right) = 0,$$

(42)

where the second equality follows from symmetry. As a result, $E_{i,0} [\Theta_T] = E_0[\Theta_T]$ almost surely for all $i$, and that $E_{i,0} [\Theta_T] = E_{j,0} [\Theta_T]$ almost surely for all $i, j$. This is contradictory to Definition 1. As a result, $\beta_2 < \beta_1 = 1$.

Now, suppose it is not the case that $\beta_h$ is strictly decreasing in $h$. There exists a smallest $h^* > 1$ such that $\beta_{h^*+1} = \beta_{h^*}$.

If $h^* = 2k$ for some $k \geq 1$. From conditions (39) and (40), we have $\text{Var} \left( E_{i,0} \left[ E_k^k[\Theta_T] \right] \right) = \text{Var} \left( E_0^{k+1}[\Theta_T] \right)$. Following a similar argument as condition (42), we have $E_{i,0} \left[ E_k^k[\Theta_T] \right] = E_0^{k+1}[\Theta_T]$ almost surely. We henceforth have

$$\text{Cov} \left( E_0^k[\Theta_T], E_0^{k+1}[\Theta_T] \right) = \text{Cov} \left( E_{i,0} \left[ E_0^{k-1}[\Theta_T] \right], E_0^{k+1}[\Theta_T] \right) = \text{Cov} \left( E_{i,0} \left[ E_0^{k-1}[\Theta_T] \right], E_{i,0} \left[ E_k^k[\Theta_T] \right] \right)$$

$$= \text{Cov} \left( E_{i,0} \left[ E_0^{k-1}[\Theta_T] \right], E_0^k[\Theta_T] \right) = \text{Cov} \left( E_0^k[\Theta_T], E_0^k[\Theta_T] \right),$$

where the first and the last equalities follow from symmetry, the second equality follows from the fact that $E_{i,0} \left[ E_k^k[\Theta_T] \right] = E_0^{k+1}[\Theta_T]$ almost surely, and the third equality follows from the law of iterated expectations. This expression means $\beta_{h^*-1} = \beta_{2k-1} = \beta_{2k} = \beta_{h^*}$, contradictory to the fact that $h^*$ is the smallest such that $\beta_{h^*+1} = \beta_{h^*}$.

If $h^* = 2k - 1$ for some $k \geq 2$, from conditions (39) and (40), we have $\text{Var} \left( E_{i,0} \left[ E_k^k[\Theta_T] \right] \right) = \text{Var} \left( E_0^k[\Theta_T] \right)$. Following a similar argument as condition (41) for all $i$, $E_{i,0} \left[ E_k^k[\Theta_T] \right] = E_0^k[\Theta_T]$ almost surely. We henceforth have

$$\text{Var} \left( E_0^k[\Theta_T] \right) = \text{Cov} \left( E_0^{k-1}[\Theta_T], E_0^{k+1}[\Theta_T] \right) = \text{Cov} \left( E_0^{k-1}[\Theta_T], E_{i,0} \left[ E_k^k[\Theta_T] \right] \right)$$

$$= \text{Cov} \left( E_0^{k-1}[\Theta_T], E_0^k[\Theta_T] \right) = \text{Cov} \left( E_0^{k-1}[\Theta_T], E_{i,0} \left[ E_0^{k-1}[\Theta_T] \right] \right) = \text{Var} \left( E_{i,0} \left[ E_0^{k-1}[\Theta_T] \right] \right),$$

where the first equality follows a similar argument as condition (38), the second and fourth equalities follow from symmetry, the third equality follows from $E_{i,0} \left[ E_k^k[\Theta_T] \right] = E_0^k[\Theta_T]$ almost surely, and the last equality follows from the law of iterated expectations. This expression means $\beta_{h^*-1} = \beta_{2k-2} = \beta_{2k-1} = \beta_{h^*}$, contradictory to the fact that $h^*$ is the smallest such that $\beta_{h^*+1} = \beta_{h^*}$. As a result, $\beta_h$ is strictly decreasing in $h$.

Finally, $\beta_h$ strictly decreasing in $h$ means that $\beta_h < \beta_1 = 1$, $\forall h \geq 2$. This also means $\beta_h > 0$ $\forall h$. If not, there exists a $h^*$ such that $\beta_{h^*} = 0$. From strict monotonicity, we have $\beta_{h^*+1} < \beta_{h^*} = 0$. This contradicts
that $\beta_{h^*+1} \geq 0$. This finishes the proof of Lemma 3.

**Proof of Corollary 1.** Corollary 1 follows directly from part (ii) of Theorem 1.

**Proof of Theorem 2.** For notation simplicity, we extend the definition of $s_{h,\tau} = \sum_{r=1}^{h} \chi_{r,\tau}$ for all $h > \tau$. In the case that $h > \tau$, from Lemma 2, we have $\chi_{h,\tau} = 0$. As a result, $s_{h,\tau} = s_{\tau,\tau}$ for all $h > \tau$. We also define $s_{0,\tau} = 0$ for all $\tau \geq 1$.

From condition (36) and the expression of $\chi_{h,\tau}$ in condition (37), we have

$$s_{h,\tau} = \gamma^{\tau-1} (\gamma + \alpha) + \sum_{l=1}^{\tau-1} \alpha \gamma^{l-1} s_{h-1,\tau-l} \quad \forall h \geq 1 \text{ and } \tau \geq 1. \quad (43)$$

Now, for all $\tau \geq 1$, as $\chi_{h,\tau} = 0$ for $h > \tau$, we can use $d_{\tau} = s_{\tau,\tau}$ denote the combined effect of beliefs of all different orders. From condition (43), we have

$$d_{\tau} = \gamma^{\tau-1} (\gamma + \alpha) + \sum_{l=1}^{\tau-1} \alpha \gamma^{l-1} d_{\tau-l} \quad \forall \tau \geq 1, \quad (44)$$

where we use the fact that $s_{h,\tau} = s_{\tau,\tau}$ for all $h > \tau$. From condition (44), we can easily verify, by induction, that

$$d_{\tau} = (\gamma + \alpha)^{\tau} \quad \forall \tau \geq 1. \quad (45)$$

For any $h \geq 1$, we now prove that $s_{h,\tau}/s_{\tau,\tau} = s_{h,\tau}/d_{\tau}$, strictly decreases with $\tau \geq h$. Notice that from condition (43), we have, for all $\tau \geq h \geq 1$

$$s_{h,\tau+1} = \gamma^{\tau} (\gamma + \alpha) + \alpha s_{h-1,\tau} + \sum_{l=1}^{\tau-1} \alpha \gamma^{l-1} s_{h-1,\tau-l} \quad \forall h \geq 1 \text{ and } \tau \geq 1.$$

$$= \gamma s_{h,\tau} + \alpha s_{h-1,\tau} < (\gamma + \alpha) s_{h,\tau}. \quad (46)$$

Also note that from condition (45), we have $s_{\tau+1,\tau+1} = d_{\tau+1} = (\gamma + \alpha) d_{\tau} = (\gamma + \alpha) s_{\tau,\tau}$. Together, we have $s_{h,\tau+1}/s_{\tau+1,\tau+1} < s_{h,\tau}/s_{\tau,\tau}$ for all $\tau \geq h \geq 1$.

Finally, we prove that, for any $h \geq 1$, $s_{h,\tau}/s_{\tau,\tau} \to 0$ as $\tau \to +\infty$. Because $s_{1,\tau} = \gamma^{\tau-1} (\gamma + \alpha)$ and $s_{\tau,\tau} = (\gamma + \alpha)^{\tau}$, $\lim_{\tau \to \infty} s_{h,\tau}/s_{\tau,\tau} \to 0$ holds for $h = 1$. Suppose there is some $h$ such that $\lim_{\tau \to \infty} s_{h,\tau}/s_{\tau,\tau} \to 0$ does not hold, let $h^* > 1$ be the smallest of such $h$. As $s_{h^*,\tau}/s_{\tau,\tau}$ is strictly decreasing in $\tau$, there exists $\Gamma > 0$ such that $\lim_{\tau \to \infty} s_{h^*,\tau}/s_{\tau,\tau} \to \Gamma$. From conditions (45) and (46), we have

$$\frac{s_{h^*,\tau+1}}{s_{\tau+1,\tau+1}} = \frac{\gamma}{\gamma + \alpha} \frac{s_{h^*,\tau}}{s_{\tau,\tau}} + \frac{\alpha}{\gamma + \alpha} \frac{s_{h^*,\tau-1}}{s_{\tau,\tau}}.$$

Let $\tau \to +\infty$, we have $\Gamma = \frac{\gamma}{\gamma + \alpha} \Gamma$. This cannot be true as $\alpha, \gamma > 0$. As a result, $\lim_{\tau \to \infty} s_{h,\tau}/s_{\tau,\tau} \to 0$ for all $h \geq 1$.

**Proof of Theorem 1.** Part (i) follows directly from projecting $a_0$ on $E_0[\Theta_T]$ and letting $\phi_T$ be the coefficient of this projection and $\epsilon$ the residual.
As a result, limₜ→∞ ϕₜ = ϕₜ, which is condition (19) in the main text. Together with the expression of $\phi^*_T$, condition (17), and the fact that $\beta_h < 1$ for all $h \geq 2$ (from Lemma 2), we have $\phi_T / \phi^*_T < 1$ for all $T \geq 2$.

To prove part (iii), from condition (19), we have $\phi_T / \phi^*_T = \left[ \sum_{h=1}^{T-1} s_{h,T} (\beta_h - \beta_{h+1}) + s_{T,T} \beta_T \right] / s_{T,T}$ and $\phi_{T+1} / \phi^*_T = \left[ \sum_{h=1}^{T-1} s_{h,T+1} (\beta_h - \beta_{h+1}) + s_{T,T+1} (\beta_T - \beta_{T+1}) + s_{T+1,T+1} \beta_{T+1} \right] / s_{T+1,T+1}$. From Lemma 2 we know $\beta_h > \beta_{h+1}$ for all $h$. Together with Theorem 2, we have, for all $T \geq 1$,

$$\phi_{T+1} / \phi^*_T = \left[ \sum_{h=1}^{T-1} s_{h,T+1} (\beta_h - \beta_{h+1}) + s_{T+1,T+1} (\beta_T - \beta_{T+1}) + s_{T+1,T+1} \beta_{T+1} \right] / s_{T+1,T+1}$$

$$= \left[ \sum_{h=1}^{T-1} s_{h,T+1} (\beta_h - \beta_{h+1}) + s_{T+1,T+1} \beta_T \right] / s_{T+1,T+1}$$

$$\leq \left[ \sum_{h=1}^{T-1} s_{h,T} (\beta_h - \beta_{h+1}) + s_{T,T} \beta_T \right] / s_{T,T} = \phi_T / \phi^*_T.$$

**Proof of Proposition 3.** By Theorem 1, the ratio $\frac{\phi_T}{\phi^*_T}$ is strictly decreasing in $T$ and bounded in $(0, 1)$. It follows that $\frac{\phi_T}{\phi^*_T}$ necessarily converges to some $\varphi \in [0, 1)$ as $T \to \infty$. Similarly, by Lemma 3, $\beta_h$ is strictly decreasing in $T$ and bounded in $(0, 1)$. It follows that $\beta_h$ necessarily converges to some $\beta \in [0, 1)$ as $T \to \infty$.

We first prove $\varphi = \beta \equiv \lim_{h \to \infty} \beta_h$. We note that for, any $\vartheta > 0$, there exists a $h^*$, such that $|\beta_h - \beta_0| < \vartheta$ for all $h \geq h^*$. From Theorem 2, we can then find $T^* \in \mathbb{N}_+$ such that, for all $T \geq T^*$, $\frac{s_{h^*,T}}{s_{T,T}} \leq \frac{\vartheta}{2}$. Together with conditions (17) and (19), we have, for all $T \geq T^*$,

$$\frac{\phi_T}{\phi^*_T} - \beta = \left| \sum_{h=1}^{T} \chi_{h,T} (\beta_h - \beta_0) \right| = \left| \sum_{h=1}^{h^*-1} \chi_{h,T} (\beta_h - \beta_0) + \sum_{h=h^*}^{T} \chi_{h,T} (\beta_h - \beta_0) \right|$$

$$\leq \sum_{h=1}^{h^*-1} \chi_{h,T} s_{T,T} + \sum_{h=h^*}^{T} \chi_{h,T} s_{T,T} \frac{\vartheta}{2}$$

$$\leq \frac{\vartheta}{2} + \frac{\vartheta}{2} = \vartheta,$$

where the first inequality we use the fact that $|\beta_h - \beta_0| \leq 1$ and the second inequality uses the fact that $\sum_{h=1}^{T} \chi_{h,T} s_{T,T} \leq \frac{s_{T,T}}{s_{T,T}} = 1$. As a result, $\varphi \equiv \lim_{T \to \infty} \frac{\phi_T}{\phi^*_T} = \beta$.

Finally, from condition (40), we know $\beta_{2h-1} = \frac{\text{Var} (\hat{E}^h_{\Theta_T})}{\text{Var} (E^h_{\Theta_T})}$. If $\lim_{h \to \infty} \text{Var} (\hat{E}^h_{\Theta_T}) = 0$, we have $\lim_{h \to \infty} \beta_{2h-1} = 0$. As $\beta_h$ is decreasing in $h$, we also have

$$\beta = \lim_{h \to \infty} \beta_h = 0.$$  \hspace{1cm} (47)

As a result, $\lim_{T \to \infty} \frac{\phi_T}{\phi^*_T} = 0$. 

42
Proof of Proposition 4. Under the assumed information structure, we have for any $h \in \{1,\ldots,T\}$ and $0 \leq t_1 < t_2 < \cdots < t_h < T$,

$$\hat{E}_{t_1}[\hat{E}_{t_2}[\ldots[\hat{E}_{t_h}[\Theta_T]\ldots]]] = \lambda^h z.$$ (48)

Now we prove by induction that, for all $t \leq T - 1$,

$$a_t = (\gamma + \alpha) \Pi_{\tau=t+1}^{T-1} (\gamma + \lambda \alpha) \hat{E}_t[\Theta_T],$$ (49)

Since $\Theta_t = 0$ for all $t \neq T$, together with condition (15), we have $a_T = \Theta_T$ and $a_{T-1} = (\gamma + \alpha) \hat{E}_{T-1}[\Theta_T]$. As a result, condition (49) holds for $t = T - 1$. Now, pick a $t \leq T - 2$, assume that the claim holds for all $\tau \in \{t + 1,\ldots,T - 1\}$, and let us prove that it also holds for $t$. Using the claim for all $\tau \in \{t + 1,\ldots,T - 1\}$, condition (15), and condition (48), we have, for $t \leq T - 2$,

$$a_t = \gamma^{T-t} \hat{E}_t[\Theta_T] + \alpha \hat{E}_t[a_{t+1}] + \alpha \sum_{k=2}^{T-t} \gamma^{k-1} \hat{E}_t[a_{t+k}];$$

$$\gamma \hat{E}_t[a_{t+1}] = \lambda \gamma^{T-t} \hat{E}_t[\Theta_T] + \lambda \alpha \sum_{k=2}^{T-t} \gamma^{k-1} \hat{E}_t[a_{t+k}].$$

As a result, we have $a_t = (\frac{\gamma}{\lambda} + \alpha) \hat{E}_t[a_{t+1}]$. Together with condition (49) for $t + 1$, we have

$$a_t = (\gamma + \alpha) \Pi_{\tau=t+1}^{T-1} (\gamma + \lambda \alpha) \hat{E}_t[\Theta_T].$$

This proves condition (49) for all $t \leq T - 1$. As a result, $\phi_T = (\gamma + \alpha) \Pi_{t=1}^{T-1} (\gamma + \lambda \alpha)$. Together with the fact that $\phi_T^* = (\gamma + \alpha)^T$. This proves Proposition 4.

Proof of Lemma 4. As firms have complete information, the canonical NKPC in condition (9) holds. Substituting it into the consumption beauty contest, condition (5), and using the fact that future markup shocks are unpredictable, we have

$$\tilde{y}_t = -\sigma \tilde{R}_t - \sigma \sum_{k=1}^{\infty} \beta^k \hat{E}_t^c[\tilde{R}_{t+k}] + \sum_{k=1}^{\infty} (1 - \beta + k \sigma \kappa) \beta^{k-1} \hat{E}_t^c[\tilde{y}_{t+k}].$$

Proof of Proposition 5. Let $\{\tilde{y}_t^{\text{trap}}, \tilde{\pi}_t^{\text{trap}}\}_{t=0}^{T}$ denote the path of output and inflation that obtains when the nominal interest rate at all periods after, and including, $T$ is fixed at its steady state value (meaning that $\tilde{R}_t = 0$ for all $t \geq T$); think of this as the “liquidity trap” path. From conditions (8) and (9), we have, for all $t \leq T - 1$,

$$\tilde{y}_t - \tilde{y}_t^{\text{trap}} = \sigma E_t[\tilde{\pi}_{t+1} - \tilde{\pi}_t^{\text{trap}}] + E_t[\tilde{y}_{t+1} - \tilde{y}_t^{\text{trap}}];$$ (50)

$$\tilde{\pi}_t - \tilde{\pi}_t^{\text{trap}} = \kappa E_t[\tilde{y}_{t+1} - \tilde{y}_t^{\text{trap}}] + \beta E_t[\tilde{\pi}_{t+1} - \tilde{\pi}_t^{\text{trap}}].$$ (51)

Now we will prove the following stronger result, which nests the representation in condition (24): there
exists non-negative scalars $\{\phi_\tau^*, \varpi_\tau^*\}_{\tau \geq 0}$ such that, whenever Assumptions 2 hold and $z$ is commonly known, the equilibrium spending and inflation at any $t \leq T$ are given by

$$\tilde{y}_t - \tilde{y}_t^{trap} = -\phi_{T-t}^* \cdot E_t[\tilde{R}_T],$$

$$\tilde{\pi}_t - \tilde{\pi}_t^{trap} = \kappa \left( \tilde{y}_t - \tilde{y}_t^{trap} \right) - \varpi_{T-t}^* \cdot E_t[\tilde{R}_T].$$

We prove this result by induction, starting with $t = T$ and proceeding backwards. When $t = T$, under Assumption 2, we have

$$\tilde{y}_T - \tilde{y}_T^{trap} = -\sigma \tilde{R}_T$$

and

$$\tilde{\pi}_T - \tilde{\pi}_T^{trap} = \kappa \left( \tilde{y}_T - \tilde{y}_T^{trap} \right).$$

This verifies (52) and (53) for $t = T$, with

$$\phi_0^* = \sigma \quad \text{and} \quad \varpi_0^* = 0.$$  

Now suppose that the result holds for arbitrary $t \in \{1, \ldots, T\}$ and let's prove that it also holds for $t - 1$. By the assumption that (52) and (53) hold at $t$ along with the Law of Iterated Expectations and the assumption, we have

$$E_{t-1}[\tilde{y}_t - \tilde{y}_t^{trap}] = -\phi_{T-t}^* \cdot E_{t-1}[\tilde{R}_T],$$

$$E_{t-1}[\tilde{\pi}_t - \tilde{\pi}_t^{trap}] = -\left( \kappa \phi_{T-t}^* + \varpi_{T-t}^* \right) \cdot E_{t-1}[\tilde{R}_T].$$

Using the above together with conditions (50) and (51) verifies that (52) and (53) hold also for $t - 1$, with

$$\phi_{T-t}^* = (1 + \sigma \kappa) \phi_{T-t}^* + \sigma \varpi_{T-t}^*,$$

$$\varpi_{T-t}^* = \beta \kappa \phi_{T-t}^* + \beta \varpi_{T-t}^*.$$  

This completes the proof and gives a recursive formula that can be used to compute $\phi^*(T)$.

Now we prove the Proposition. From conditions (55) and (56), we have that, for all $\tau \geq 0$,

$$\phi_{\tau+1}^* = (1 + \sigma \kappa) \phi_\tau^* + \sigma \varpi_\tau^*,$$

$$\varpi_{\tau+1}^* = \beta \kappa \phi_\tau^* + \beta \varpi_\tau^*.$$  

Together with condition (54), we know, when $\kappa > 0$, $\varpi_\tau^* > 0$, $\forall \tau \geq 1$. Then, from equation (57), we have $\phi_\tau^* > \sigma$, $\forall \tau \geq 1$, and $\phi_\tau^*$ is strictly increasing in $\tau$. Moreover, when $\kappa > 0$, $1 + \sigma \kappa > 1$. From (57), we know $\phi_\tau^*$ explodes to infinity as $\tau \to \infty$.

Finally, we prove a few more results useful for the rest of the paper. First, we prove a recursive relationship about $\{\phi_\tau^*\}_{\tau \geq 0}$.

$$\frac{\phi_{\tau+1}^*}{\phi_\tau^*} + \beta \frac{\phi_{\tau-1}^*}{\phi_\tau^*} = 1 + \beta + \sigma \kappa \quad \forall \tau \geq 1.$$  

From condition (57), we have, for all $\tau \geq 1$,

$$\beta \phi_\tau^* = (1 + \sigma \kappa) \phi_{\tau-1}^* + \sigma \beta \varpi_{\tau-1}^*.$$
Together with conditions (57) and (58), we arrive at condition (59).

Second, we prove that, when \( \kappa > 0 \),

\[
\frac{\phi_r^*}{\phi_{r-1}^*} \text{ is strictly increasing in } \tau \geq 1. \tag{60}
\]

From conditions (57) and (58), we have \( \phi_1^* = \sigma (1 + \kappa) \) and \( \phi_2^* = \sigma \left( (1 + \kappa)^2 + \kappa \beta \right) \). As a result, when \( \kappa > 0 \),

\[
\frac{\phi_2^*}{\phi_1^*} = 1 + \kappa + \frac{\sigma \kappa \beta}{1 + \kappa} > \frac{\phi_1^*}{\phi_0^*}.
\]

Now we proceed by induction. Suppose that, for \( \tau \geq 1 \), we have \( \frac{\phi_{r+1}^*}{\phi_r^*} > \frac{\phi_1^*}{\phi_0^*} \). From condition (59), we know

\[
\frac{\phi_{r+2}^*}{\phi_{r+1}^*} + \beta \frac{\phi_r^*}{\phi_{r-1}^*} = 1 + \beta + \kappa \quad \forall \tau \geq 1.
\]

Together with \( \frac{\phi_{r+1}^*}{\phi_r^*} > \frac{\phi_1^*}{\phi_0^*} \), we have \( \frac{\phi_{r+2}^*}{\phi_{r+1}^*} > \frac{\phi_1^*}{\phi_0^*} \). This proves (60).

Finally, from condition (59), we know \( \frac{\phi_r^*}{\phi_{r-1}^*} \) is bounded above. Together with (60), \( \frac{\phi_r^*}{\phi_{r-1}^*} \) must converge to \( \Gamma^* > 0 \), as \( \tau \to \infty \). From condition (59) again, we know \( \Gamma^* \) satisfy

\[
\Gamma^* + \beta \frac{1}{\Gamma^*} = 1 + \beta + \kappa. \tag{61}
\]

Proof of Proposition 6. With \( \{ \tilde{y}_t^{\text{trap}}, \tilde{\pi}_t^{\text{trap}} \}_{t=0}^T \) defined as in the proof of Proposition 5, we can rewrite the two beauty contests as follows:

\[
\tilde{y}_t - \tilde{y}_t^{\text{trap}} = -\sigma \beta^{T-t} E_t[\tilde{R}_T] + \sum_{k=1}^{T-t} \sigma \beta^{k-1} E_t \left[ \tilde{\pi}_{t+k} - \tilde{\pi}_{t+k}^{\text{trap}} \right] + (1 - \beta) \sum_{k=1}^{T-t} \beta^{k-1} E_t \left[ \tilde{y}_{t+k} - \tilde{y}_{t+k}^{\text{trap}} \right], \tag{62}
\]

\[
\tilde{\pi}_t - \tilde{\pi}_t^{\text{trap}} = \sum_{k=0}^{T-t} (\beta \theta)^k E_t \left[ \tilde{y}_{t+k} - \tilde{y}_{t+k}^{\text{trap}} \right] + \frac{1-\theta}{\theta} \sum_{k=1}^{T-t} (\beta \theta)^k E_t \left[ \tilde{\pi}_{t+k} - \tilde{\pi}_{t+k}^{\text{trap}} \right]. \tag{63}
\]

Consider the following claim: Under Assumption 3, there exists functions \( \phi, \varpi : (0, 1] \times (0, 1] \times \mathbb{N} \to \mathbb{R}_{\geq 0} \) such that, for any \( t \leq T - 1 \),

\[
\tilde{y}_t - \tilde{y}_t^{\text{trap}} = -\phi (\lambda_c, \lambda_f, T - t) E_t^c [\tilde{R}_T], \tag{64}
\]

\[
\tilde{\pi}_t - \tilde{\pi}_t^{\text{trap}} = \kappa \left( \tilde{y}_t - \tilde{y}_t^{\text{trap}} \right) - \varpi (\lambda_c, \lambda_f, T - t) E_t^f [\tilde{R}_T]. \tag{65}
\]

In the rest of this proof, we establish this claim by induction. The result stated in the proposition is then nested by taking \( t = 0 \).

First, consider \( t = T - 1 \). From conditions (62) and (6) along with the fact that it is common knowledge
monetary policy replicates flexible-price allocations from \( T + 1 \) and on, we have

\[
\tilde{y}_T - \tilde{y}_T^{\text{trap}} = -\sigma \tilde{R}_T \quad \text{and} \quad \tilde{\pi}_T - \tilde{\pi}_T^{\text{trap}} = \kappa \left( \tilde{y}_T - \tilde{y}_T^{\text{trap}} \right),
\]

and therefore

\[
\tilde{y}_{T-1} - \tilde{y}_{T-1}^{\text{trap}} = -\sigma (1 + \sigma \kappa) \tilde{E}_T^{c}[\tilde{R}_T],
\]

\[
\tilde{\pi}_{T-1} - \tilde{\pi}_{T-1}^{\text{trap}} = \kappa \left( \tilde{y}_{T-1} - \tilde{y}_{T-1}^{\text{trap}} \right) - \sigma \kappa \beta \tilde{E}_T^{f}[\tilde{R}_T].
\]

It follows that the claim holds for \( t = T - 1 \) with

\[
\phi(\lambda_c, \lambda_f, 1) = \sigma (1 + \sigma \kappa) \quad \text{and} \quad \varpi(\lambda_c, \lambda_f, 1) = \sigma \kappa \beta. \tag{66}
\]

Now, pick an arbitrary \( t \leq T - 2 \), assume that conditions (64) and (65) hold for all \( \tau \in \{t + 1, \ldots, T - 1\} \), and let us prove that it also holds for \( t \). Since the claim holds for \( \tau \in \{t + 1, \ldots, T - 1\} \), and since \( \tilde{y}_T = -\sigma \tilde{R}_T \) and \( \tilde{\pi}_T = -\kappa \sigma \tilde{R}_T + \tilde{\mu}_T \), from condition (62), we have

\[
\tilde{y}_t - \tilde{y}_t^{\text{trap}} = -\sigma \beta^{T-t-1} (1 + \sigma \kappa) \tilde{E}_t^{c}[\tilde{R}_T] - (1 - \beta + \sigma \kappa) \sum_{k=1}^{T-t-1} \beta^{k-1} \phi(\lambda_c, \lambda_f, T - t - k) \tilde{E}_t^{c}[\tilde{E}_{t+k}^{c}[\tilde{R}_T]]
\]

\[
- \sigma \sum_{k=1}^{T-t-1} \beta^{k-1} \varpi(\lambda_c, \lambda_f, T - t - k) \tilde{E}_t^{f}[\tilde{E}_{t+k}^{f}[\tilde{R}_T]]
\]

\[
= - \left\{ \sigma \beta^{T-t-1} (1 + \sigma \kappa) + \sum_{k=1}^{T-t-1} \beta^{k-1} [(1 - \beta + \sigma \kappa) \lambda_c \phi(\lambda_c, \lambda_f, T - t - k) + \sigma \lambda_f \varpi(\lambda_c, \lambda_f, T - t - k)] \right\} \tilde{E}_t^{c}[\tilde{R}_T]
\]

where we have used the fact that, under Assumption 3, for \( 1 \leq k \leq T - t - 1 \),

\[
\tilde{E}_t^{c}[\tilde{E}_{t+k}^{c}[\tilde{R}_T]] = \lambda_c \tilde{E}_t^{c}[\tilde{R}_T] \quad \text{and} \quad \tilde{E}_t^{c}[\tilde{E}_{t+k}^{f}[\tilde{R}_T]] = \lambda_f \tilde{E}_t^{c}[\tilde{R}_T]. \tag{67}
\]

This proves the part of the claim that regards output, condition (64), with

\[
\phi(\lambda_c, \lambda_f, T - t) = \sigma \beta^{T-t-1} (1 + \sigma \kappa) + \sum_{k=1}^{T-t-1} \beta^{k-1} [(1 - \beta + \sigma \kappa) \lambda_c \phi(\lambda_c, \lambda_f, T - t - k) + \sigma \lambda_f \varpi(\lambda_c, \lambda_f, T - t - k)]. \tag{68}
\]

46
Similarly, the inflation beauty contest in condition (63) gives
\[
\tilde{\pi}_t - \tilde{\pi}_t^{\text{trap}} = \kappa \left( \tilde{y}_t - \tilde{y}_t^{\text{trap}} \right) + \tilde{\mu}_t - \sigma \frac{\kappa}{\beta} (\beta \theta)^{T-t} E_t^f[\tilde{R}_T] - (\kappa + \frac{1}{2} \theta) \sum_{k=1}^{T-t-1} (\beta \theta)^k \phi(\lambda_c, \lambda_f, T - t - k) E_t^f[E_{t+k}^c[\tilde{R}_T]]
\]
\[
- \frac{1}{\theta} \sum_{k=1}^{T-t-1} (\beta \theta)^k \varpi(\lambda_c, \lambda_f, T - t - k) E_t^f[E_{t+k}^f[\tilde{R}_T]] - \sigma \left( \kappa + \frac{1}{2} \theta \right) (\beta \theta)^{T-t} \tilde{E}_t^f[\tilde{R}_T]
\]
\[
= \kappa \left( \tilde{y}_t - \tilde{y}_t^{\text{trap}} \right) + \tilde{\mu}_t
\]
\[
- \left\{ \sigma \frac{\kappa}{\beta} (\beta \theta)^{T-t} - \sum_{k=1}^{T-t-1} (\beta \theta)^k \left[ \frac{\kappa \lambda_c}{\beta} \phi(\lambda_c, \lambda_f, T - t - k) + \frac{1}{2} \frac{\lambda_f}{\beta} \varpi(\lambda_c, \lambda_f, T - t - k) \right] \right\} \tilde{E}_t^f[\tilde{R}_T],
\]
where we have used the fact that, similarly to the consumers’ case, for \(1 \leq k \leq T - t - 1\),
\[
E_t^f[E_{t+k}^c[\tilde{R}_T]] = \lambda_c E_t^f[\tilde{R}_T] \quad \text{and} \quad E_t^f[E_{t+k}^f[\tilde{R}_T]] = \lambda_f E_t^f[\tilde{R}_T].
\]
This proves the part of the claim that regards inflation, condition (65) with
\[
\varpi(\lambda_c, \lambda_f, T - t) = \sigma \frac{\kappa}{\beta} (\beta \theta)^{T-t} - \sum_{k=1}^{T-t-1} (\beta \theta)^k \left[ \frac{\kappa \lambda_c}{\beta} \phi(\lambda_c, \lambda_f, T - t - k) + \frac{1}{2} \frac{\lambda_f}{\beta} \varpi(\lambda_c, \lambda_f, T - t - k) \right].
\]
(70)
We finally provide a recursive formula for computing \(\phi(\lambda_c, \lambda_f, T - t)\) and \(\varpi(\lambda_c, \lambda_f, T - t)\), which will be useful later. From condition (68), we have, for \(t \leq T - 2\),
\[
\phi(\lambda_c, \lambda_f, T - t) = \beta \phi(\lambda_c, \lambda_f, T - t - 1) + (1 - \beta + \sigma \kappa) \lambda_c \phi(\lambda_c, \lambda_f, T - t - 1) + \sigma \lambda_f \varpi(\lambda_c, \lambda_f, T - t - 1)
\]
\[
= (\beta + (1 - \beta + \sigma \kappa) \lambda_c) \phi(\lambda_c, \lambda_f, T - t - 1) + \sigma \lambda_f \varpi(\lambda_c, \lambda_f, T - t - 1).
\]
(71)
Similarly, from condition (70), we have, for \(t \leq T - 2\),
\[
\varpi(\lambda_c, \lambda_f, T - t) = \beta \theta \varpi(\lambda_c, \lambda_f, T - t - 1) + \beta \theta \left[ \frac{\kappa \lambda_c}{\beta} \phi(\lambda_c, \lambda_f, T - t - 1) + \frac{1}{2} \frac{\lambda_f}{\beta} \varpi(\lambda_c, \lambda_f, T - t - 1) \right]
\]
\[
= \kappa \beta \lambda_c \phi(\lambda_c, \lambda_f, T - t - 1) + \beta [\theta + (1 - \theta) \lambda_f] \varpi(\lambda_c, \lambda_f, T - t - 1).
\]
(72)
From now on, to simplify notation, we use \(\phi_\tau\) and \(\varpi_\tau\) as shortcuts for, respectively, \(\phi(\lambda_c, \lambda_f, \tau)\) and \(\varpi(\lambda_c, \lambda_f, \tau)\).
We first prove part (i) of Proposition 6. From condition (68), we know \(\phi_\tau > \sigma \beta^\tau\). The fact that \(\phi_\tau < \phi_\tau^*\) is a direct corollary from the monotonicity of \(\phi_\tau\) with respect to \(\lambda_c\) and \(\lambda_f\), which will be proved shortly.
We then prove part (ii) of Proposition 6. When \(\kappa > 0\), from conditions (66), (71) and (72), we know that \(\phi_\tau, \varpi_\tau > 0\) for all \(\tau \geq 1\).
We will first prove, for \(\tau \geq 2\), \(\phi_\tau = \phi(\lambda_c, \lambda_f, \tau)\) is strictly increasing in both \(\lambda_c\) and \(\lambda_f\). We will proceed by induction on \(\tau\). For \(\tau = 2\), from (66), (71) and (72), we have \(\phi_2\) and \(\varpi_2\) is strictly increasing in both \(\lambda_c\) and \(\lambda_f\). Suppose for \(\tau \geq 2\), \(\phi_\tau, \varpi_\tau\) is strictly increasing in both \(\lambda_c\) and \(\lambda_f\). From conditions (71) and (72),
we know $\phi_{r+1}$ and $\varpi_{r+1}$ are strictly increasing in both $\lambda_c$ and $\lambda_f$, where we use the fact that $\phi_r, \varpi_r > 0$. This proves that, for $\tau \geq 2$, $\phi_r = \phi(\lambda_c, \lambda_f, \tau)$ is strictly increasing in both $\lambda_c$ and $\lambda_f$. Because of the strict monotonicity, we have, for $\tau \geq 2$, whenever $\lambda_c < 1$ and/or $\lambda_f < 1$, $\frac{\partial \phi_r}{\partial \tau} = \frac{\phi(\lambda_c, \lambda_f, \tau)}{\phi(\lambda_c, \lambda_f, \tau)} < 1$.

We now prove that, whenever $\lambda_c < 1$ and/or $\lambda_f < 1$, the ratio $\frac{\phi_r}{\phi_r} = \frac{\phi(\lambda_c, \lambda_f, \tau)}{\phi(\lambda_c, \lambda_f, \tau)}$ is strictly decreasing in $\tau \geq 1$. We start by noticing, from the proof of Proposition 5, we have, for $\tau \geq 3$,

$$\frac{\phi_r}{\phi_r} + \beta \frac{\phi_r-2}{\phi_r-1} = 1 + \beta + \sigma \kappa .$$ (73)

Now we prove that $\phi_r$ satisfies an inequality with a similar form as (73):

$$\frac{\phi_r}{\phi_r} + \beta \frac{\phi_r-2}{\phi_r-1} \leq 1 + \beta + \sigma \kappa \lambda_c < 1 + \beta + \sigma \kappa \quad \forall \tau \geq 3. \quad (74)$$

From condition (71), we have, for $\tau \geq 3$,

$$\phi_r = (\beta + (1 - \beta) \lambda_c) \phi_{r-1} + \sigma \kappa \lambda_c \phi_{r-1} + \sigma \lambda_f \varpi_{r-1},$$

$$\frac{\beta}{\beta + (1 - \beta) \lambda_c} \phi_{r-1} = \beta \phi_{r-2} + \frac{\sigma \beta \lambda_c}{\beta + (1 - \beta) \lambda_c} \phi_{r-2} + \frac{\sigma \beta \lambda_f}{\beta + (1 - \beta) \lambda_c} \varpi_{r-2}.$$

From the previous two conditions, we have, for $\tau \geq 3$,

$$\phi_r + \beta \phi_{r-2} = (\beta + (1 - \beta) \lambda_c) \phi_{r-1} + \sigma \kappa \lambda_c \phi_{r-1} + \sigma \lambda_f \varpi_{r-1}$$

$$+ \frac{\beta}{\beta + (1 - \beta) \lambda_c} \phi_{r-1} - \frac{\sigma \beta \lambda_c}{\beta + (1 - \beta) \lambda_c} \phi_{r-2} - \frac{\sigma \beta \lambda_f}{\beta + (1 - \beta) \lambda_c} \varpi_{r-2}.$$

Note that, for $\tau \geq 3$ and $\lambda_c, \lambda_f \in (0, 1)$, from condition (72), we have

$$\left[ (\beta + (1 - \beta) \lambda_c) + \sigma \kappa \lambda_c + \frac{\beta}{\beta + (1 - \beta) \lambda_c} \right] \phi_{r-1} \leq (1 + \beta + \sigma \kappa \lambda_c) \phi_{r-1},$$

and

$$\sigma \lambda_f \varpi_{r-1} - \frac{\sigma \beta \lambda_c}{\beta + (1 - \beta) \lambda_c} \phi_{r-2} - \frac{\sigma \beta \lambda_f}{\beta + (1 - \beta) \lambda_c} \varpi_{r-2}$$

$$= \sigma \lambda_f \left( \kappa \beta \lambda_c \phi_{r-2} + \beta [\theta + (1 - \theta) \lambda_f] \varpi_{r-2} \right) - \frac{\sigma \beta \lambda_c}{\beta + (1 - \beta) \lambda_c} \phi_{r-2} - \frac{\sigma \beta \lambda_f}{\beta + (1 - \beta) \lambda_c} \varpi_{r-2}$$

$$= \sigma \kappa \beta \lambda_c \left( \lambda_f - \frac{1}{\beta + (1 - \beta) \lambda_c} \right) \phi_{r-2} + \sigma \beta \lambda_f \left[ \theta + (1 - \theta) \lambda_f - \frac{1}{\beta + (1 - \beta) \lambda_c} \right] \varpi_{r-2}$$

$$\leq 0.$$

Together with condition (75), we arrive at condition (74).

Now we can prove that, whenever $\lambda_c < 1$ and/or $\lambda_f < 1$, $\frac{\phi_r}{\phi_r}$ is strictly decreasing in $\tau$. We already prove $\frac{\phi_2}{\phi_1} < 1 = \frac{\phi_1}{\phi_1}$. We proceed by induction on $\tau$. If $\frac{\phi_r}{\phi_{r-1}} < \frac{\phi_{r-1}}{\phi_{r-1}}$ for $\tau \geq 2$, we have $\frac{\phi_{r-1}}{\phi_{r-1}} > \frac{\phi_{r-2}}{\phi_{r-2}}$. From
(73) and (74), we have \( \frac{\phi_{\tau+1}}{\phi_{\tau}} < \frac{\phi_{\tau+1}}{\phi_{\tau}} \) and thus \( \frac{\phi_{\tau+1}}{\phi_{\tau+1}} < \frac{\phi_{\tau}}{\phi_{\tau}} \). This finishes the proof that \( \frac{\phi_{\tau}}{\phi_{\tau}} \) is strictly decreasing in \( \tau \geq 1 \), whenever \( \lambda_c < 1 \) and/or \( \lambda_f < 1 \).

Now we prove that, whenever \( \lambda_c < 1 \) and/or \( \lambda_f < 1 \), \( \frac{\phi_{\tau}}{\phi_{\tau}} \) converges to 0 as \( \tau \to \infty \). Because \( \frac{\phi_{\tau}}{\phi_{\tau}} > 0 \) is strictly decreasing in \( \tau \geq 1 \), there exists \( \Gamma \in (0,1) \) such that \( \frac{\phi_{\tau}}{\phi_{\tau}} \to \Gamma \) as \( \tau \to \infty \). We next prove by contradiction that \( \Gamma = 0 \).

Suppose first that \( \lambda_c < 1 \). If \( \Gamma > 0 \), we have \( \frac{\phi_{\tau}}{\phi_{\tau-1}} \to 1 \) as \( \tau \to \infty \). Because \( \frac{\phi_{1}}{\phi_{1-1}} \to \Gamma^* \), we have \( \frac{\phi_{\tau}}{\phi_{\tau-1}} \to \Gamma^* \) and \( \frac{\phi_{\tau+1}}{\phi_{\tau+1}} \to \frac{1}{\Gamma^*} \) as \( \tau \to \infty \). From condition (61), we have \( \frac{\phi_{\tau}}{\phi_{\tau-1}} + \beta \frac{\phi_{\tau+1}}{\phi_{\tau+1}} \to 1 + \beta + \kappa \) as \( \tau \to \infty \). However, this is inconsistent with (74) when \( \lambda_c < 1 \) and \( \kappa > 0 \). As a result, \( \Gamma = 0 \).

Suppose next that \( \lambda_c = 1 \) but \( \lambda_f < 1 \). We prove a stronger version of (74):

\[
\frac{\phi_{\tau}}{\phi_{\tau-1}} + (1 + \sigma \kappa (1 - \lambda_f)) \beta \frac{\phi_{\tau-2}}{\phi_{\tau-1}} \leq 1 + \beta + \sigma \kappa \quad \forall \tau \geq 3. \tag{76}
\]

From conditions (71) and (72), we have, for \( \tau \geq 3 \),

\[
\phi_{\tau} = (1 + \sigma \kappa) \phi_{\tau-1} + \sigma \lambda_f \varpi_{\tau-1},
\]

\[
\beta \phi_{\tau-1} = \beta \phi_{\tau-2} + \beta \sigma \kappa \phi_{\tau-2} + \beta \sigma \lambda_f \varpi_{\tau-2},
\]

\[
\varpi_{\tau-1} = \kappa \beta \phi_{\tau-2} + \beta [\theta + (1 - \theta) \lambda_f] \varpi_{\tau-2}.
\]

As a result, for \( \tau \geq 3 \),

\[
\phi_{\tau} + \beta \phi_{\tau-2} = (1 + \sigma \kappa + \beta) \phi_{\tau-1} + \sigma \lambda_f \varpi_{\tau-1} - \beta \sigma \kappa \phi_{\tau-2} - \beta \sigma \lambda_f \varpi_{\tau-2}
\]

\[
\leq (1 + \sigma \kappa + \beta) \phi_{\tau-1} + \sigma (\lambda_f - 1) \kappa \beta \phi_{\tau-2}.
\]

This proves (76).

Now, if \( \Gamma > 0 \), similarly, we have \( \frac{\phi_{\tau}}{\phi_{\tau-1}} \to 1 \) as \( \tau \to \infty \). Because \( \frac{\phi_{1}}{\phi_{1-1}} \to \Gamma^* \), we have \( \frac{\phi_{\tau}}{\phi_{\tau-1}} \to \Gamma^* \) and \( \frac{\phi_{\tau+1}}{\phi_{\tau+1}} \to \frac{1}{\Gamma^*} \) as \( \tau \to \infty \). From condition (61), we have \( \frac{\phi_{\tau}}{\phi_{\tau-1}} + (1 + \sigma \kappa (1 - \lambda_f)) \beta \frac{\phi_{\tau+1}}{\phi_{\tau+1}} \to 1 + \beta + \sigma \kappa + \sigma \kappa (1 - \lambda_f) \beta + \frac{1}{\Gamma^*} \) as \( \tau \to \infty \). However, this is inconsistent with equation (74) when \( \lambda_f < 1 \). As a result, \( \Gamma = 0 \) when \( \lambda_c = 1 \), but \( \lambda_f < 1 \).

Finally, we prove that, when \( \lambda_c \) is sufficiently low, \( \phi(\lambda_c, \lambda_f, \tau) \) converges to zero as \( \tau \to \infty \). The eigenvalues of the dynamical system \( (\phi_{\tau}, \varpi_{\tau}) \) based on conditions (71) and (72) are

\[
m_1 = \frac{\beta + (1 - \beta + \sigma \kappa) \lambda_c + \beta [(1 - \theta) \lambda_f + \theta] - \sqrt{(\beta + (1 - \beta + \sigma \kappa) \lambda_c - \beta [(1 - \theta) \lambda_f + \theta])^2 + 4 \sigma \beta \lambda_f \lambda_c \kappa}}{2} > 0
\]

\[
m_2 = \frac{\beta + (1 - \beta + \sigma \kappa) \lambda_c + \beta [(1 - \theta) \lambda_f + \theta] + \sqrt{(\beta + (1 - \beta + \sigma \kappa) \lambda_c - \beta [(1 - \theta) \lambda_f + \theta])^2 + 4 \sigma \beta \lambda_f \lambda_c \kappa}}{2} > m_1.
\]

Note that \( \lim_{\lambda_c \to 0} m_2 = \beta < 1 \). As a result, when \( \lambda_c \) is sufficiently low, both eigenvalues are below 1, which means that \( \phi(\lambda_c, \lambda_f, \tau) \) converges to zero as \( \tau \to \infty \).
Proof of Proposition 7. We use $\tilde{g}_t$ to denote the amount of government spending at period $t$. As mentioned in main text, the government spending $\tilde{g}_t$ is financed by lump sum tax at period $t$, $\tilde{t}_t = \tilde{g}_t$. Similar as the analysis for monetary policy, we assume $\tilde{g}_t$ becomes commonly known at period $t$ and only allow higher-order uncertainty about future $\tilde{g}$.

Similar as the main text, now we start to work with log-linearized representation. Because the introduction of lump-sum tax, the individual budget constraint becomes

$$\sum_{k=0}^{+\infty} \beta^k \bar{c}_{i,t+k} = \bar{a}_{i,t} + \sum_{k=0}^{+\infty} \beta^k \left\{ \Omega_1 (\bar{w}_{i,t+k} + \bar{n}_{i,t+k}) + \Omega_2 \bar{c}_{i,t+k} - (\Omega_1 + \Omega_2 - 1)\tilde{t}_t \right\},$$

where $\Omega_1$ is the ratio of labor income to total income (net of tax) in steady state, $\Omega_2$ is the ratio of dividend income to total income (net of tax) in steady state, and $(\Omega_1 + \Omega_2 - 1)$ is the ratio of lump sum tax to total income (net of tax) in steady state. On the other hand, the individual optimal labor supply and Euler equation, conditions (28) and (29), still hold here. Together, this gives rise to the optimal expenditure of consumer $i \in \mathcal{I}_e$ in period $t$,

$$\tilde{c}_{i,t} = \frac{e (1-\beta)}{e+\Omega_1} \bar{a}_{i,t} - \sum_{k=1}^{+\infty} \beta^k \bar{E}_{i,t} \left[ \bar{v}_{t+k} \right] + (1-\beta) \left[ \frac{(e+1)\Omega_1}{e+\Omega_1} \bar{w}_{i,t} + \frac{e\Omega_2}{e+\Omega_1} \bar{c}_{i,t} - \frac{e(\Omega_1 + \Omega_2 - 1)}{e+\Omega_1} \tilde{t}_t \right] + (1-\beta) \sum_{k=1}^{+\infty} \beta^k \bar{E}_{i,t} \left[ \frac{(e+1)\Omega_1}{e+\Omega_1} \bar{w}_{i,t+k} + \frac{e\Omega_2}{e+\Omega_1} \bar{c}_{i,t+k} - \frac{e(\Omega_1 + \Omega_2 - 1)}{e+\Omega_1} \tilde{t}_t \right].$$

Using the fact that assets average to zero and that future idiosyncratic shocks are unpredictable, we obtain the following condition for aggregate spending:

$$\tilde{c}_t = -\sum_{k=1}^{+\infty} \beta^k \bar{E}^c_{t} \left[ \bar{v}_{t+k} \right] + (1-\beta) \left[ \frac{(e+1)\Omega_1}{e+\Omega_1} \bar{w}_t + \frac{e\Omega_2}{e+\Omega_1} \bar{c}_t - \frac{e(\Omega_1 + \Omega_2 - 1)}{e+\Omega_1} \tilde{t}_t \right] + (1-\beta) \sum_{k=1}^{+\infty} \beta^k \bar{E}^c_{t} \left[ \frac{(e+1)\Omega_1}{e+\Omega_1} \bar{w}_{t+k} + \frac{e\Omega_2}{e+\Omega_1} \bar{c}_{t+k} - \frac{e(\Omega_1 + \Omega_2 - 1)}{e+\Omega_1} \tilde{t}_t \right].$$

The firm side, on the other hand, is essentially same as the case without government, as a result, condition (6) still holds, but the formula for marginal cost are different. In particular, from the production function (3) and the optimal labor supply condition (28), we have

$$mc_t = \bar{w}_t = e \int \bar{a}_{i,t} di + \bar{c}_t = e\tilde{y}_t + \bar{c}_t = (e\Omega_3 + 1) \bar{c}_t + e (1 - \Omega_3) \tilde{g}_t,$$

where $\tilde{y}_t = \Omega_3 \bar{c}_t + (1 - \Omega_3) \tilde{g}_t$, $\Omega_3 = \frac{1}{e(1 + \Omega_2)}$ is the steady state consumption to output ratio, and $1 - \Omega_3 = \frac{\Omega_1 + \Omega_2 - 1}{\Omega_1 + \Omega_2}$ is the steady state government spending to output ratio. As a result, the inflation beauty contest

---

48In steady state, the ratio of government spending to consumption will be equal to ratio of lump sum tax to total income (net of tax), $\Omega_1 + \Omega_2 - 1$. This explains the formula for $\Omega_3$. 

50
in condition (6) can be written as
\[ \tilde{\pi}_t = \kappa (\Omega_c \tilde{c}_t + (1 - \Omega_c) \tilde{g}_t) + \kappa \sum_{k=1}^{+\infty} (\beta \theta)^k \tilde{E}_t [\Omega_c \tilde{c}_{t+k} + (1 - \Omega_c) \tilde{g}_{t+k}] + \frac{1-\bar{\theta}}{\bar{\theta}} \sum_{k=1}^{+\infty} (\beta \theta)^k \tilde{E}_t [\tilde{\pi}_{t+k}] + \tilde{\mu}_t, \]
where \( \Omega_c = \frac{\epsilon \Omega + 1}{\epsilon + 1} \).

Finally, note that the real profit of monopolist \( j \) at period \( t \) is given by \( \epsilon^j_t = \left( \frac{\bar{p}_j}{\bar{p}_j} - w^j_t \right) y^j_t \). After log-linearization, we have \( \tilde{c}_t = -\frac{\Omega_1}{\Omega_2} \tilde{w}_t + \tilde{y}_t = -\frac{\Omega_1}{\Omega_2} \tilde{w}_t + \tilde{y}_t \).

Together with condition (79), we have, for all \( t \),
\[
\frac{(\epsilon+1)\Omega_1}{\epsilon+\Omega_1} \tilde{w}_t + \frac{(\epsilon+1)\Omega_1}{\epsilon+\Omega_1} \tilde{e}_t - \frac{\epsilon(\Omega_1 + \Omega_2 - 1)}{\epsilon + \Omega_1} \tilde{t}_t = \frac{(\epsilon+1)\Omega_1}{\epsilon+\Omega_1} \tilde{w}_t + \frac{(\epsilon+1)\Omega_1}{\epsilon+\Omega_1} \tilde{y}_t - \frac{\epsilon(\Omega_1 + \Omega_2 - 1)}{\epsilon + \Omega_1} \tilde{g}_t \\
= \frac{\Omega_1}{\epsilon + \Omega_1} \tilde{w}_t + \frac{\Omega_1}{\epsilon + \Omega_1} \tilde{y}_t - \frac{\epsilon(\Omega_1 + \Omega_2 - 1)}{\epsilon + \Omega_1} \tilde{g}_t \\
= \frac{\epsilon(\Omega_1 + \Omega_2)}{\epsilon + \Omega_1} \tilde{c}_t + \frac{\Omega_1 + \Omega_2 - 1}{\Omega_1 + \Omega_2} \tilde{g}_t + \frac{\Omega_1}{\epsilon + \Omega_1} \tilde{c}_t - \frac{\epsilon(\Omega_1 + \Omega_2 - 1)}{\epsilon + \Omega_1} \tilde{g}_t \\
= \tilde{c}_t
\]
Substitute it into condition (78), we have
\[ \tilde{c}_t = -\sigma \sum_{k=1}^{+\infty} \beta^{k-1} \tilde{E}_t [\tilde{t}_{t+k}] + \frac{1-\beta}{\beta} \left( \sum_{k=1}^{+\infty} \beta^k \tilde{E}_t [\tilde{c}_{t+k}] \right). \]
This is exactly the same form of the consumption beauty contest, as condition (5).

Now let us state Proposition 7 formally here. Similar as Assumption 2, we assume \( \tilde{y}_T = z + \eta \), where \( z \) and \( \eta \) are random variables, independent of one another and of any other shock in the economy, with \( z \sim N(0, \sigma_z^2) \) and \( \eta \sim N(0, \sigma_\eta^2) \). The former is realized at \( t = 0 \), and could be interpreted as news about government spending; the latter is realized at \( t = T \) and is unpredictable prior to that point.

First consider the complete information outcome. Suppose \( z \) is commonly known starting at \( t = 0 \), we can find a scalar \( \phi^*_{g,T} \) such that \( \tilde{c}_0 - \tilde{c}_{0,trap} = \phi^*_{g,T} \tilde{E}_0 [\tilde{g}_T] \), where \( \tilde{c}_{0,trap} \) denotes the “liquidity trap” level of consumption (i.e., the one obtained when it is common knowledge that \( \tilde{y}_T = 0 \)). We have, when \( \kappa > 0 \),
\[ \phi^*_{g,T} > 0, \] is strictly increasing in \( T \), and diverges to infinity as \( T \to \infty \).

Now consider the case in which \( z \) is not common knowledge. Similar as Section 6, we consider the information structure specified in Assumption 3, in which let each agent receives a private signal about \( z \)
\footnote{This expression is equivalent to \( \frac{\Omega_1}{\Omega_2 + 1} \tilde{e}_t + \frac{\Omega_1}{\Omega_2 + 1} \tilde{w}_t + \tilde{g}_t = \frac{\Omega_1}{\Omega_2 + 1} \tilde{e}_t + \frac{\Omega_1}{\Omega_2 + 1} \left( \tilde{w}_t + \int_t^T \tilde{r}_t \, dt \right) = \tilde{y}_t \). The last equation is true because \( \frac{\Omega_1}{\Omega_2 + 1} \) is steady state labor income to total income ratio (before deducting tax) and \( \frac{\Omega_2}{\Omega_2 + 1} \) is steady state dividend income to total income ratio (before deducting tax).}
at period 0. We can then find a scalar \( \phi_{g,T} \) such that \( \tilde{c}_0 = \phi_{g,T}^* E_0^c [\tilde{g}_T] \). We have, as long as \( \kappa > 0 \) and information is incomplete, that is \( \lambda_c < 1 \),\(^{50}\)

\[
\phi_{g,T} \in (0, \phi_{g,T}^*) \text{ is strictly increasing in } \lambda_c \text{ and } \lambda_f;
\]

the ratio \( \phi_{g,T}/\phi_{g,T}^* \) is strictly decreasing in \( T \) and converges to 0 as \( T \to \infty \);

finally, when \( \lambda_c \) is sufficiently low, \( \phi_{g,T} \) also converges to 0 as \( T \to \infty \). \( \tag{83} \)

We start from the proof of condition (82). Similar as the proof Proposition 5, we can establish that there exists non-negative scalars \( \{ \phi_{g,T}^*, \omega_{g,T}^* \}_{t \geq 0} \) such that, when \( z \) is commonly known, the equilibrium spending and inflation at any \( t \leq T \) are given by

\[
\tilde{c}_t - \tilde{c}_t^{trap} = \phi^*_g (T - t) \cdot E_t [\tilde{g}_T],
\]

\[
\tilde{\pi}_t - \tilde{\pi}_t^{trap} = \kappa \left( \Omega_c (\tilde{c}_t - \tilde{c}_t^{trap}) + (1 - \Omega_c) \tilde{g}_t \right) + \omega^*_g (T - t) \cdot E_t [\tilde{R}_T],
\]

where \( \tilde{c}_t^{trap} \) and \( \tilde{\pi}_t^{trap} \) denotes the “liquidity trap” level of consumption and inflation (i.e., the one obtained when it is common knowledge that \( \tilde{g}_T = 0 \).) We will use a version of Euler condition and NKPC as conditions (8) and (9):

\[
\tilde{c}_t = -\sigma \left\{ \tilde{R}_t - E_t [\tilde{\pi}_{t+1}] \right\} + E_t [\tilde{c}_{t+1}]
\]

\[
\tilde{\pi}_t = \kappa \left( \Omega_c \tilde{c}_t + (1 - \Omega_c) \tilde{g}_t \right) + \beta E_t [\tilde{\pi}_{t+1}] + \tilde{\mu}_t.
\]

Using the above expressions, similar as the proof of Proposition 5, we can establish that \( \phi_{g,0}^* = 0, \omega_{g,0}^* = 0, \phi_{g,1}^* = \sigma \kappa (1 - \Omega_c), \omega_{g,1}^* = \beta \kappa (1 - \Omega_c), \) and for all \( \tau \geq 1, \)

\[
\phi_{g,\tau+1}^* = (1 + \sigma \kappa \Omega_c) \phi_{g,\tau}^* + \sigma \omega_{g,\tau}^*,
\]

\[
\omega_{g,\tau+1}^* = \beta \kappa \Omega_c \phi_{g,\tau}^* + \beta \omega_{g,\tau}^*. \tag{88} \]

From condition (88), we can see when \( \kappa > 0, \phi_{g,\tau}^* \) is positive, strictly increasing in \( \tau \) and diverges to infinity. This proves condition (82). Similar as condition (59), one can also prove the following recursive relationship about \( \phi_{g}^* \):

\[
\frac{\phi_{g,\tau+1}^*}{\phi_{g,\tau}^*} + \beta \frac{\phi_{g,\tau-1}^*}{\phi_{g,\tau}^*} = 1 + \beta + \sigma \kappa \Omega_c \quad \forall \tau \geq 1. \tag{90} \]

Moreover, as condition (61), we know \( \frac{\phi_{g,\tau}^*}{\phi_{g,\tau-1}^*} \) must converge to \( \Gamma_g^* > 0 \), as \( \tau \to \infty \):

\[
\Gamma_g^* + \beta \frac{1}{\Gamma_g^*} = 1 + \beta + \sigma \kappa \Omega_c. \tag{91} \]

\(^{50}\)We allow \( \lambda_f \in (0, 1] \). In other words, we nest the case in which firms have perfect knowledge about \( z \).
We now turn to the case of incomplete information and establish the proof of condition (83). Similar as the proof of Proposition 6, we can find \( \tilde{\phi}_g, \tilde{\omega}_g : (0, 1] \times (0, 1] \times \mathbb{N} \to \mathbb{R}_{\geq 0} \) such that, for any \( t \leq T - 1 \),

\[
\tilde{c}_t - \tilde{c}_t^{\text{trap}} = \phi_g (\lambda_c, \lambda_f, T - t) \tilde{E}_t^c [\tilde{g}_T],
\]

\[
\tilde{\pi}_t - \tilde{\pi}_t^{\text{trap}} = \kappa \left( \Omega_c \left( \tilde{c}_t - \tilde{c}_t^{\text{trap}} \right) + (1 - \Omega_c) \tilde{g}_t \right) + \tilde{\omega}_g (\lambda_c, \lambda_f, T - t) \tilde{E}_t^f [\tilde{R}_T].
\]

Using conditions (80) and (81), we have \( \phi_g (\lambda_c, \lambda_f, 1) = \sigma \kappa (1 - \Omega_c) \), \( \tilde{\omega}_g (\lambda_c, \lambda_f, 1) = \beta \kappa (1 - \Omega_c) \) and, for all \( \tau \geq 2 \),

\[
\phi_g (\lambda_c, \lambda_f, \tau) = \sigma \beta^{\tau - 1} (1 - \Omega_c) \kappa + \sum_{k=1}^{\tau-1} \beta^{k-1} \left[ (1 - \beta + \sigma \kappa \Omega_c) \lambda_c \phi_g (\lambda_c, \lambda_f, \tau - k) + \sigma \lambda_f \tilde{\omega}_g (\lambda_c, \lambda_f, \tau - k) \right];
\]

\[
\tilde{\omega}_g (\lambda_c, \lambda_f, \tau) = \left( 1 - \Omega_c \right) \frac{\kappa}{\theta} (\beta \theta)^{T-t} + \sum_{k=1}^{\tau-1} (\beta \theta)^k \left( \frac{\kappa \lambda_c \Omega_c}{\theta} \phi_g (\lambda_c, \lambda_f, \tau - k) + \frac{1}{\theta} \frac{\lambda_f}{\theta} \tilde{\omega}_g (\lambda_c, \lambda_f, \tau - k) \right).
\]

Together, we can establish, for all \( \tau \geq 2 \),

\[
\phi_g (\lambda_c, \lambda_f, \tau) = (\beta + (1 - \beta + \sigma \kappa \Omega_c) \lambda_c) \phi_g (\lambda_c, \lambda_f, \tau - 1) + \sigma \lambda_f \tilde{\omega}_g (\lambda_c, \lambda_f, \tau - 1);
\]

\[
\tilde{\omega}_g (\lambda_c, \lambda_f, \tau) = \kappa \beta \lambda_c \Omega_c \phi_g (\lambda_c, \lambda_f, \tau - 1) + \beta [\theta + (1 - \theta) \lambda_f] \tilde{\omega}_g (\lambda_c, \lambda_f, \tau - 1).
\]

From the above conditions, we can see that for all \( \tau \geq 2 \), \( \phi_{g, \tau} = \phi_g (\lambda_c, \lambda_f, \tau) \) is strictly increasing in \( \lambda_c \) and \( \lambda_f \).

As \( \phi_{g, \tau}^* = \phi_g (1, 1, T) \), we also have \( \phi_{g, \tau} \in (0, \phi_{g, \tau}^*) \).

Now, we now prove that, whenever \( \lambda_c < 1 \), the ratio \( \phi_{g, \tau} = \frac{\phi_{g, \lambda_c, \lambda_f, \tau}}{\phi_{g, \tau}(\tau)} \) is strictly decreasing in \( \tau \geq 1 \) and converges to 0 as \( \tau \to \infty \). To this goal, similar as condition (74), we try to establish that

\[
\frac{\phi_{g, \tau}}{\phi_{g, \tau-1}} + \beta \frac{\phi_{g, \tau-2}}{\phi_{g, \tau-1}} \leq 1 + \beta + \sigma \kappa \Omega_c \lambda_c < 1 + \beta + \sigma \kappa \Omega_c \quad \forall \tau \geq 3.
\]

From condition (96), we have, for \( \tau \geq 3 \),

\[
\phi_{g, \tau} = (\beta + (1 - \beta) \lambda_c) \phi_{g, \tau-1} + \sigma \kappa \Omega_c \lambda_c \phi_{g, \tau-1} + \sigma \lambda_f \tilde{\omega}_{g, \tau-1} + \sigma \beta \lambda_f \tilde{\omega}_{g, \tau-2}.
\]

From the previous two conditions, we have, for \( \tau \geq 3 \),

\[
\phi_{g, \tau} + \beta \phi_{g, \tau-2} = (\beta + (1 - \beta) \lambda_c) \phi_{g, \tau-1} + \sigma \kappa \Omega_c \lambda_c \phi_{g, \tau-1} + \sigma \lambda_f \tilde{\omega}_{g, \tau-1} + \sigma \beta \lambda_f \tilde{\omega}_{g, \tau-2}.
\]
Note that, for $\tau \geq 3$ and $\lambda_c, \lambda_f \in (0, 1)$, from condition (97), we have

\[
\left[(\beta + (1 - \beta)\lambda_c) + \sigma\kappa\Omega_c\lambda_c + \frac{\beta}{\beta + (1 - \beta)\lambda_c}\right] \phi_{g, \tau - 1} \leq (1 + \beta + \sigma\kappa\Omega_c\lambda_c) \phi_{g, \tau - 1},
\]

and

\[
\sigma \lambda_f \varpi_{g, \tau - 1} - \frac{\sigma\beta\kappa\Omega_c\lambda_c}{\beta + (1 - \beta)\lambda_c} \phi_{g, \tau - 2} - \frac{\sigma\beta\lambda_f}{\beta + (1 - \beta)\lambda_c} \varpi_{g, \tau - 2} = \sigma \lambda_f (\kappa\beta\lambda_c\Omega_c \phi_{g, \tau - 2} + \beta [\theta + (1 - \theta)\lambda_f] \varpi_{g, \tau - 2}) - \frac{\sigma\beta\kappa\Omega_c\lambda_c}{\beta + (1 - \beta)\lambda_c} \phi_{g, \tau - 2} - \frac{\sigma\beta\lambda_f}{\beta + (1 - \beta)\lambda_c} \varpi_{g, \tau - 2} = \sigma\kappa\Omega_c\lambda_c \left(\lambda_f - \frac{1}{\beta + (1 - \beta)\lambda_c}\right) \phi_{g, \tau - 2} + \sigma\beta\lambda_f \left[\theta + (1 - \theta)\lambda_f - \frac{1}{\beta + (1 - \beta)\lambda_c}\right] \varpi_{g, \tau - 2} \leq 0.
\]

Together with condition (99), we reach at condition (98). To prove $\frac{\partial \phi_{g, \tau}}{\partial \tau}$ is strictly decreasing in $\tau$, note that we already prove that $\frac{\partial \phi_{g, 2}}{\partial \tau} < 1 = \frac{\partial \phi_{g, 1}}{\partial \tau}$. We proceed by induction on $\tau$. If $\frac{\partial \phi_{g, \tau}}{\partial \tau} < \frac{\partial \phi_{g, \tau - 1}}{\partial \tau}$ for $\tau \geq 2$, we have $\phi_{g, \tau - 1} > \phi_{g, \tau - 1}$. From (90) and (98), we have $\frac{\partial \phi_{g, \tau + 1}}{\partial \phi_{g, \tau}} < \frac{\partial \phi_{g, \tau + 1}}{\partial \phi_{g, \tau - 1}}$ and thus $\phi_{g, \tau + 1} < \phi_{g, \tau}$. This finishes the proof that $\frac{\partial \phi_{g, \tau}}{\partial \tau}$ is strictly decreasing in $\tau \geq 1$.

To prove that $\frac{\partial \phi_{g, \tau}}{\partial \tau}$ converges to 0 as $\tau \to \infty$. Because $\frac{\partial \phi_{g, \tau}}{\partial \tau} > 0$ is strictly decreasing in $\tau \geq 1$, there exists $\Gamma_g \in [0, 1)$ such that $\frac{\partial \phi_{g, \tau}}{\partial \tau} \to \Gamma_g$ as $\tau \to \infty$. If $\Gamma_g > 0$, we have $\frac{\partial \phi_{g, \tau}}{\partial \phi_{g, \tau - 1}} \to 1$ as $\tau \to \infty$. Because $\frac{\partial \phi_{g, \tau}}{\partial \phi_{g, \tau - 1}} \to \Gamma_g$, we have $\frac{\partial \phi_{g, \tau}}{\partial \phi_{g, \tau - 1}} \to \Gamma_g$ and $\frac{\partial \phi_{g, \tau - 1}}{\partial \phi_{g, \tau - 1}} \to \frac{1}{\Gamma_g}$ as $\tau \to \infty$. From condition (91), we have $\frac{\partial \phi_{g, \tau}}{\partial \phi_{g, \tau - 1}} + \beta \frac{\partial \phi_{g, \tau - 1}}{\partial \phi_{g, \tau - 1}} \to 1 + \beta + \sigma\kappa\Omega_c$ as $\tau \to \infty$. However, this is inconsistent with (98) when $\lambda_c < 1$ and $\kappa > 0$. As a result, $\Gamma_g = 0$.

Finally, we prove that, when $\lambda_c$ is sufficiently low, $\phi_{g}(\lambda_c, \lambda_f, \tau)$ converges to zero as $\tau \to \infty$. The eigenvalues of the dynamical system $(\phi_{g, \tau}, \varpi_{g, \tau})$ based on conditions (71) and (72) are

\[
m_1 = \frac{\beta + (1 - \beta + \sigma\kappa\Omega_c)\lambda_c + \beta [(1 - \theta)\lambda_f + \theta]}{2} - \frac{\sqrt{(\beta + (1 - \beta + \sigma\kappa\Omega_c)\lambda_c - \beta [(1 - \theta)\lambda_f + \theta])^2 + 4\sigma\beta\lambda_f\lambda_c\varpi_{g, \kappa}^2}}{2} > 0; \]

\[
m_2 = \frac{\beta + (1 - \beta + \sigma\kappa\Omega_c)\lambda_c + \beta [(1 - \theta)\lambda_f + \theta]}{2} + \frac{\sqrt{(\beta + (1 - \beta + \sigma\kappa\Omega_c)\lambda_c - \beta [(1 - \theta)\lambda_f + \theta])^2 + 4\sigma\beta\lambda_f\lambda_c\varpi_{g, \kappa}^2}}{2} > m_1; \]

Note that $\lim_{\lambda_c \to 0} m_2 = \beta < 1$. As a result, when $\lambda_c$ is sufficiently low, both eigenvalues are below 1, which means that $\phi_{g}(\lambda_c, \lambda_f, \tau)$ converges to zero as $\tau \to \infty$. 

54
Appendix B. Learning

In this appendix, we first prove that Theorem 1 holds for two leading forms of learning studied in the literature. We next prove that an asymptotic version of the result holds for arbitrary forms of learning, provided that higher-order uncertainty is bounded away from zero, in a sense to be made precise.

Horizon effects with sticky information or noisy private learning Consider the following two cases of learning.

Case 1. Agents become gradually aware of $\Theta_T \sim N(0, \sigma_0^2)$, as in Mankiw and Reis (2002) and Wiederholt (2015). Specially, at each period $t \in \{0, \ldots, T-1\}$, a fraction $\lambda_{sticky}$ of agents who have not become aware about $\Theta_T$ become aware about $\Theta_T$. $\Theta_T$ becomes commonly known at period $T$.

Case 2. Agents receive a new private signal about $\Theta_T \sim N(0, \sigma_0^2)$ in each period, as in Woodford (2003a), Nimark (2008), and Mackowiak and Wiederholt (2009). In each period $t \in \{0, \ldots, T-1\}$, each agent $i$’s new information about $\Theta_T$ can be summarized by a private signal of $\Theta_T$: $s_{i,t} = \Theta_T + v_{i,t}$, with $v_{i,t} \sim N(0, \sigma_{v,t}^2)$, i.i.d across $i$ and $t$, and independent with respect to $\Theta_T$.

In both cases, there exists $\{\lambda_t\}_{t=0}^{T-1}$ such that, for all $t$, $\lambda_t \in (0, 1)$ and, for any $h \in \{1, \ldots, T\}$ and $0 \leq t_1 < t_2 < \cdots < t_h < T$,

$$E_{t_1}[E_{t_2}[\ldots[E_{t_h}[\Theta_T]\ldots]]] = \lambda_{t_1} \cdots \lambda_{t_h} \Theta_T,$$

with $\lambda_t = 1 - (1 - \lambda_{sticky})^{t+1}$ in case 1 and $\lambda_t = \frac{\sum_{r=0}^{t} \sigma_{v,t}^2}{\sum_{r=0}^{t} \sigma_{v,t+1}^2}$ in case 2.

Now we prove by induction that, for all $t \leq T - 1$,

$$a_t = (\gamma + \alpha) \Pi_{t+1}^{T-1} (\gamma + \alpha t) E_t[\Theta_T].$$

(101)

Since $\Theta_T = 0$ for all $t \neq T$, together with condition (15), we have $a_T = \Theta_T$ and $a_{T-1} = (\gamma + \alpha) E_{T-1}[\Theta_T]$. As a result, condition (101) holds for $t = T - 1$. Now, pick a $t \leq T - 2$, assume that the claim holds for all $\tau \in \{t+1, \ldots, T-1\}$, and let us prove that it also holds for $t$. Using the claim for all $\tau \in \{t+1, \ldots, T-1\}$, condition (15), and condition (100), we have, for $t \leq T - 2$,

$$a_t = \gamma^{T-t} E_t[\Theta_T] + \alpha E_t[a_{t+1}] + \alpha \sum_{k=2}^{T-t} \gamma^{k-1} E_t[a_{t+k}] ;$$

$$\gamma E_t[a_{t+1}] = \lambda_{t+1} \gamma^{T-t} E_t[\Theta_T] + \alpha \lambda_{t+1} \sum_{k=2}^{T-t} \gamma^{k-1} E_t[a_{t+k}].$$

As a result, we have $a_t = \left(\frac{\gamma}{\lambda_{t+1}} + \alpha\right) E_t[a_{t+1}]$. Together with condition (101) for $t + 1$, we have

$$a_t = (\gamma + \alpha) \Pi_{t+1}^{T-1} (\gamma + \lambda_{t+1} \alpha) E_t[\Theta_T].$$

This proves condition (101) for all $t \leq T - 1$. As a result, $\phi_T = (\gamma + \alpha) \Pi_{t=1}^{T-1} (\gamma + \lambda_t \alpha)$. Together with the
fact that $\lambda_t \in (0, 1)$ and $\phi_T^* = (\gamma + \alpha)^T$, we prove Theorem 1 for the case with learning.

**The limit property with arbitrary learning.** As noted in the main text, it is possible to prove, under quite general conditions, an asymptotic version of our horizon effect: as long as the higher-order uncertainty is bounded away from zero (in a sense we make precise now), the scalar $\phi_T$ becomes vanishingly small relative to $\phi_T^*$ as $T \to \infty$.

For any $t \leq T - 1$ and any $k \in \{1, \ldots, T-t\}$, we henceforth let $B_t^k$ collect all the relevant $k$-order beliefs, as of period $t$:

$$B_t^k \equiv \{ x : \exists (t_1, t_2, \ldots, t_k), \text{with } t = t_1 < t_2 < \ldots < t_k \leq T - 1, \text{ such that } x = \tilde{E}_{t_1} \tilde{E}_{t_2} \ldots \tilde{E}_{t_k} [\Theta_T] \ldots \}$$

For convenience, we also let $B_t^0 \equiv \{ \Theta_T \}$. We next introduce the following assumption.

**Assumption 4 (Non-Vanishing Higher-Order Uncertainty)** There exists an $\epsilon > 0$ such that:

(i) For all $t \in \{0, \ldots, T-2\}$, there exists at least a mass $\epsilon$ of consumers such that

$$\text{Var} \left( E_t [x] | \omega_t^i \right) \geq \epsilon \text{Var} \left( E_t [x] \right),$$

for all $x \in B_t^k$, $\tau \in \{t+1, \ldots, T-1\}$, and $k \in \{0, 1, \ldots, T-\tau\}$, where $\omega_t^i$ is agent $i$’s information set at period $t$.

(ii) $\text{Var} \left( \tilde{E}_0 [\tilde{R}_T] \right) \geq \epsilon$.

To interpret this assumption, note that complete information imposes that $E_t [x]$ is known to every agent, and therefore that $\text{Var} \left( E_t [x] | \omega_t^i \right) = 0$, regardless of how volatile $E_t [x]$ itself is. By contrast, letting $\text{Var} \left( E_t [x] | \omega_t^i \right) > 0$ whenever $\text{Var} \left( E_t [x] \right) > 0$ is essentially tautological to assuming that agents have incomplete information or, equivalently, that they face higher-order uncertainty. Relative to this tautology, part (i) introduces an arbitrarily small bound on the level of higher-order uncertainty. This bound guarantees that the higher-order uncertainty does not vanish as we let $T$ go to infinity. Part (ii), on the other hand, means simply that there is non-trivial variation in first-order beliefs in the first place. The next result then follows from Theorem 1 and formalizes our point that our horizon effect, at least in its limit form, holds for arbitrary forms of learning.

**Proposition 8 (Horizon)** Under Assumption 4, the ratio $\frac{\phi_T^*}{\phi_T}$ converges to zero as $T \to \infty$.

**Proof of Proposition 8.** We first prove that, under Assumption (4),

$$\text{Var} (x) \leq (1 - \epsilon^2)^k \text{Var} (\Theta_T). \quad (102)$$

for any $x = \tilde{E}_t \tilde{E}_{t_2} \ldots \tilde{E}_{t_k} [\Theta_T] \in B_t^k$. 56
To simplify notation, let \( y = \tilde{E}_{t_2} \ldots \tilde{E}_{t_k}[\Theta_T] \) for \( k \geq 2 \), and \( y = \Theta_T \) for \( k = 1 \). From Assumption 4, we have, there is at least a mass \( \epsilon \) of consumers such that

\[
\text{Var} \left( E_t[y] | \omega^t_i \right) \geq \epsilon \text{Var} \left( E_t[y] \right).
\]

As a result,

\[
E \left[ \text{Var} \left( E_t[y] | \omega^t_i \right) | \Omega_t \right] \geq \epsilon^2 \text{Var} \left( E_t[y] \right),
\]

where \( \Omega_t \) is the cross-sectional distribution of consumer \( i \)'s information set \( \omega^t_i \) at period \( t \). Using the law of total variance, we have

\[
E \left[ \text{Var} \left( E_t[y] | \omega^t_i \right) | \Omega_t \right] + \text{Var} \left( E \left[ E_t[y] | \omega^t_i \right] \right) = E \left[ \text{Var} \left( E_t[y] | \omega^t_i \right) | \Omega_t \right] + \text{Var} \left( E \left[ y | \omega^t_i \right] \right) = \text{Var} \left( E_t[y] \right).
\]

As a result, we have\(^{31}\)

\[
\text{Var} \left( x \right) = \text{Var} \left( \tilde{E}_t \tilde{E}_{t_2} \ldots \tilde{E}_{t_k}[\Theta_T] \right) = \text{Var} \left( \tilde{E}_t[y] \right) \leq \text{Var} \left( E \left[ y | \omega^t_i \right] \right) \leq (1 - \epsilon^2) \text{Var} \left( E_t[y] \right)
\]

\[
\leq (1 - \epsilon^2) \text{Var} \left( y \right) = (1 - \epsilon^2) \text{Var} \left( \tilde{E}_{t_3} \tilde{E}_{t_4} \ldots \tilde{E}_{t_k}[\Theta_T] \right).
\]

Iterating the previous condition proves (102).

Condition (102) provides an upper bound for the variance of all \( k \)-th order belief. Together with the fact that \( \phi^*_T = s_{T,T} \) and, for any random variables \( X, Y \) and scalars \( a, b \geq 0 \),

\[
\text{Var}(aX + bY) = a^2 \text{Var}(X) + 2ab \text{Cov}(X, Y) + b^2 \text{Var}(Y)
\]

\[
\leq a^2 \text{Var}(X) + 2ab \sqrt{\text{Var}(X) \text{Var}(Y)} + b^2 \text{Var}(Y)
\]

\[
= \left( a \sqrt{\text{Var}(X)} + b \sqrt{\text{Var}(Y)} \right)^2,
\]

we have

\[
\left( \frac{\phi^*_T}{\phi_T} \right)^2 = \left( \frac{\text{Cov} \left( a_0, \tilde{E}_0[\Theta_T] \right)}{\phi^*_T \text{Var} \left( E_0[\Theta_T] \right)} \right)^2 \leq \frac{\text{Var} \left( a_0 \right)}{\phi^*_T \text{Var} \left( E_0[\Theta_T] \right)} \leq \frac{1}{\text{Var} \left( E_0[\Theta_T] \right)} \left[ \sum_{k=1}^{T} \left( \frac{X_{k,T}}{s_{T,T}} \left( 1 - \epsilon^2 \right)^{\frac{3}{2}} \sqrt{\text{Var} \left( \Theta_T \right)} \right) \right]^2
\]

\[
= \left[ \sum_{k=1}^{T} \left( \frac{X_{k,T}}{s_{T,T}} \left( 1 - \epsilon^2 \right)^{\frac{3}{2}} \right) \right]^2 \frac{\text{Var} \left( \Theta_T \right)}{\text{Var} \left( E_0[\Theta_T] \right)}.
\]

For any \( \delta > 0 \), there exists \( h \in \mathbb{N}_+ \) such that \( \frac{(1-\epsilon^2)^{\frac{3}{2}}}{1-(1-\epsilon^2)^{\frac{3}{2}}} \leq \frac{\delta}{2} \). From Theorem 2, there exists \( T^* \in \mathbb{N}_+ \) such

\(^{31}\)We use the fact that for any random variable \( X \), and any information set \( I \), \( \text{Var} \left( E \left[ X | I \right] \right) \leq \text{Var} \left( X \right) \). We also use the fact that \( \tilde{E}_t \{ : \} = E \left[ E \left[ : | \omega^t_i \right] | \Omega_t \right] \), where \( \Omega_t \) is the cross sectional distribution of \( \omega^t_i \) at time \( t \).
that, for all \( T \geq T^*, \sum_{k=1}^{h-1} \frac{\chi_{k,T}}{s_{T,T}} \leq \frac{\vartheta}{T}. \) As a result, for all \( T \geq T^*, \)
\[
\sum_{k=1}^{T} \frac{\chi_{k,T}}{s_{T,T}} (1 - \epsilon^2)^{\frac{h}{2}} \leq \sum_{k=1}^{h-1} \frac{\chi_{k,T}}{s_{T,T}} + \sum_{k=h}^{T} (1 - \epsilon^2)^{\frac{h}{2}} \leq \frac{\vartheta}{2} + \frac{(1 - \epsilon^2)^{\frac{h}{2}}}{1 - (1 - \epsilon^2)^{\frac{h}{2}}} \leq \vartheta.
\]
This proves
\[
\sum_{k=1}^{T} \left( \frac{\chi_{k,T}}{s_{T,T}} (1 - \epsilon^2)^{\frac{h}{2}} \right) \to 0 \quad \text{as} \quad T \to +\infty.
\]
Together with (104) and the fact that \( \text{Var} \left( E_0[\Theta_T] \right) \geq \epsilon, \) the proof of Proposition (8) is completed.

Appendix C. Additional Results for the New-Keynesian Model

In this Appendix, we provide a few additional results regarding the application of our insights in the context of a liquidity trap. We first explain how our results regarding the forward-guidance puzzle can be understood under the lenses of a discounted Euler condition and a discounted NKPC, and draw certain connections to the literature. We next show how our insights help lessen the paradox of flexibility.

Discounted Euler Condition and Discounted NKPC. Proposition 4 has already indicated how the lack of common knowledge is akin to introducing additional discounting in the forward-looking equations of a macroeconomic model. We now illustrate how this helps recast our results regarding forward guidance and fiscal multipliers under the lenses of a discounted Euler condition and a discounted NKPC.

For the present purposes, we make a minor modification to the New-Keynesian setting used in Sections 6 and 7: we let the firms lack common knowledge of the concurrent aggregate level of consumption. This modification is not strictly needed but sharpens the representation offered below.\(^52\)

**Proposition 9** The power of forward guidance in the absence of common knowledge is the same as that in a representative-agent variant in which, for all \( t \leq T - 2, \) the Euler condition and the NKPC are modified as follows:

\[
\gamma_t = -\sigma \left\{ \bar{R}_t - \lambda_c E_t [\hat{\pi}_{t+1}] \right\} + M_c E_t [\gamma_{t+1}],
\]

(105)

\[
\hat{\pi}_t = \kappa' \gamma_t + \beta M_f E_t [\hat{\pi}_{t+1}] + \tilde{\mu}_t,
\]

(106)

where \( M_c \equiv \beta + (1 - \beta) \lambda_c \in (\beta, 1], \ M_f \equiv \theta + (1 - \theta) \lambda_f \in (\theta, 1], \) and \( \kappa' \equiv \kappa \lambda_f. \)

This result, which is analogous to Proposition 4 in our abstract setting, maps the incomplete-information \( \phi_T \) of the economy under consideration to the complete-information \( \phi_T \) of a variant economy, in which the Euler condition and the NKPC have been “discounted” in the manner described above. When we remove

\(^52\)Without this modification, the obtained representation is a bit less elegant, but the essence remains the same; see Proposition 10 in the earlier, NBER version of our paper (Angeletos and Lian, 2016a).
common knowledge, it is as if the representative consumer discounts her expectations of next period's aggregate income and inflation by a factor equal to, respectively, $M_c$ and $\lambda_c$; and it is as if the representative firm discounts the future inflation by a factor equal to $M_f$.\footnote{The change in the slope of the NKPC, from $\kappa$ to $\kappa'$, is of relative little interest to us, because the effect of the informational friction through this slope cannot be identified separately from that of a higher Frisch elasticity or less steep marginal costs.}

Consider first the discounting that shows up in the Euler condition. When $\beta$ is close to 1, $M_c$ is close to 1, even if $\lambda_c$ is close to zero. This underscores that the multiplier inside the demand block—which gets attenuated by the absence of common knowledge—is weak in the textbook version of the New-Keynesian model. As mentioned in the main text, short horizons, counter-cyclical precautionary savings, and feedback effects between housing prices and consumer spending tend to reinforce this multiplier, thereby also increasing the discounting caused by the absence of common knowledge.

Consider next the discounting that shows up in the NKPC. For the textbook parameterization of the degree of price stickiness (meaning a price revision rate, $1 - \theta$, equal to $2/3$), the effective discount factor, $M_f$, falls from 1 to .83 as we move from common knowledge ($\lambda_f = 1$) to the level of imperfection assumed in our numerical example ($\lambda_f = .75$). The magnitude of this discount helps explain the sizable effects seen in Figure 1. Under the considered parameterization, the actual response of inflation to news about future demand is greatly reduced relative the common-knowledge benchmark. The fact that the average consumer underestimates the inflation response, as well as the spending of other consumers, reinforces this effect and helps further attenuate the feedback loop between inflation and spending.

Relation to McKay, Nakamura and Steinsson (2016a) and Gabaix (2016). Related forms of discounting appear in McKay, Nakamura and Steinsson (2016a), for the Euler condition, and in Gabaix (2016), for both the Euler condition and the NKPC. In this regards, these papers and ours are complementary to one another. However, the underlying theory and its empirical manifestations are different.

McKay, Nakamura and Steinsson (2016a) obtain a discounted Euler condition at the aggregate level by introducing a specific combination of heterogeneity and market incompleteness that forces some agents to hit their borrowing constraints and breaks the individual-level Euler condition. This theory therefore ties the resolution of forward guidance to microeconomic evidence about the response of individual consumption to idiosyncratic shocks. By contrast, our theory ties the resolution of forward guidance to survey evidence about the response of average forecast errors to the underlying policy news. The two theories can therefore be quantified independently from one another—and it’s an open question which is one is more relevant in the context of forward guidance.

Gabaix (2016) on the other hand, assumes two kinds of friction. The first is that agents are less responsive to any variation in interest rates and incomes due to “sparsity” (a form of adjustment cost). The second is that agents underestimate the response of future aggregate outcomes to exogenous shocks. The first is of purely decision-theoretic nature and, as the one in McKay, Nakamura and Steinsson (2016a), amounts to a distortion of the individual-level Euler condition. The second is more closely related to the one we have
obtained here: by anchoring expectations of aggregate outcomes, it gives rise to discounting only at the aggregate level. In this regard, Gabaix’s theory and ours have a similar empirical implication: they both let the average forecast of future inflation and income respond less than the complete-information, rational-expectations, benchmark. Yet, the two theories make distinct empirical predictions in two other dimensions. First, our theory ties that inertia of the forecasts to their cross-sectional heterogeneity. Second, our theory predicts that the forecast errors, and the associated attenuation, ought to decrease as time passes, agents accumulate more information, and higher-order beliefs converge to first-order beliefs. This prediction, which is not shared by Gabaix’s approach, is validated by the evidence in Coibion and Gorodnichenko (2012).

On the Paradox of Flexibility We now consider the implications of our insights for the paradox of flexibility. In the standard model, the power of forward guidance and the fiscal multiplier vis-a-vis future government spending increase with the degree of price flexibility: $\phi_T$ increases with $\kappa$.\footnote{Whenever we vary $\kappa$, we vary $\theta$ while keeping the Frisch elasticity constant, which means that variation in $\kappa$ maps one-to-one to variation in the degree of price flexibility.} This property is directly related to the “paradox of flexibility” (Eggertsson and Krugman, 2012). The next result proves, in effect, that the mechanism identified in our paper helps diminish this paradox as well.

**Proposition 10 (Price Flexibility)** Let $\phi_T$ be the scalar characterized in either Proposition 6 or Proposition 7 and set $\lambda_f = 1$. We have $\frac{\partial \phi_T}{\partial \kappa} > 0$ and $\frac{\partial}{\partial \lambda_c} \left( \frac{\partial \phi_T}{\partial \kappa} \right) > 0$. That is, the power of forward guidance and the fiscal multiplier vis-a-vis future government spending increase with the degree of price flexibility, but at a rate that is slower the greater the departure from common knowledge.

This finding is an example of how lack of common knowledge reduces the paradox of flexibility more generally. In the standard model, a higher degree of price flexibility raises the GE effects of all kinds of demand shocks—whether these come in the form of forward guidance, discount rates, or borrowing constraints—because it intensifies the feedback loop between aggregate spending and inflation. By intensifying this kind of macroeconomic complementarity, however, a higher degree of price flexibility also raises the relative importance of higher-order beliefs, which in turn contributes to stronger attenuation effects of the type we have documented in this paper. In a nutshell, the very same mechanism that creates the paradox of flexibility within the New-Keynesian framework also helps contain that paradox once we relax the common-knowledge assumptions of that framework.

Note that we have proved the above result only under the restriction $\lambda_f = 1$, which means that only the consumers lack common knowledge. Whenever $\lambda_f < 1$, there is a conflicting effect, which is that higher price flexibility reduces the strategic complementarity that operates within the supply block, thereby also reducing the role of $\lambda_f$ itself. For the numerical example considered earlier, however, the overall effect of higher price flexibility is qualitatively the same whether $\lambda_f = 1$ or $\lambda_f = \lambda_c$.

We illustrate this in Figure 2. We let $\lambda_f = \lambda_c$, use the same parameter values as those used in Figure 1, and plot the relation between the ratio $\phi_T / \phi^*_{T}$ and the horizon $T$ under two values for $\theta$. The solid red line
corresponds to a higher value for $\theta$, while the dashed blue line corresponds to a lower value for $\theta$, that is, to more price flexibility. As evident in the figure, more price flexibility maps, not only to a lower ratio $\phi_T/\phi_T^*$ (i.e., stronger attenuation) for any given $T$, but also to a more rapid decay in that ratio as we raise $T$.

**Proof of Proposition 10** Consider first the environment studied in Section 6 and let us study the cross-partial derivative of the power of forward guidance with respect to $\kappa$ and $\lambda_c$. To simplify notation, we use $\phi_\tau$ and $\varpi_\tau$ as shortcuts for, respectively, $\phi(\lambda_c, \lambda_f, \tau)$ and $\varpi(\lambda_c, \lambda_f, \tau)$, where the functions $\phi$ and $\varpi$ are defined as in the proof of Proposition 6. From conditions (66), we have

$$\frac{\partial \phi_1}{\partial \kappa} = \frac{\partial \phi(\lambda_c, 1, 1)}{\partial \kappa} = \sigma^2 > 0 \quad \text{and} \quad \frac{\partial \varpi_1}{\partial \kappa} = \frac{\partial \varpi(\lambda_c, 1, 1)}{\partial \kappa} = \sigma \beta > 0. \quad (107)$$

For any $\tau \geq 2$, when $\lambda_f = 1$, conditions (71) and (72) become

$$\phi_\tau = (\beta + (1 - \beta + \sigma \kappa) \lambda_c) \phi_{\tau-1} + \sigma \varpi_{\tau-1} \quad \text{and} \quad \varpi_\tau = \kappa \beta \lambda_c \phi_{\tau-1} + \beta \varpi_{\tau-1}. \quad \text{As a result, for all } \tau \geq 2, \text{ we have}$$

$$\frac{\partial \phi_\tau}{\partial \kappa} = (\beta + (1 - \beta + \sigma \kappa) \lambda_c) \frac{\partial \phi_{\tau-1}}{\partial \kappa} + \sigma \lambda_c \phi_{\tau-1} + \sigma \frac{\partial \varpi_{\tau-1}}{\partial \kappa}, \quad (108)$$

$$\frac{\partial \varpi_\tau}{\partial \kappa} = \kappa \beta \lambda_c \frac{\partial \phi_{\tau-1}}{\partial \kappa} + \beta \lambda_c \phi_{\tau-1} + \beta \frac{\partial \varpi_{\tau-1}}{\partial \kappa}. \quad (109)$$

From conditions (107), (108) and (109), $\frac{\partial \phi_\tau}{\partial \kappa}$ and $\frac{\partial \varpi_\tau}{\partial \kappa}$ are strictly positive for any $\tau \geq 1$ by induction. Moreover, from conditions (66) and (107), we have that $\frac{\partial \phi_\tau}{\partial \lambda_c}$ and $\frac{\partial \varpi_\tau}{\partial \lambda_c}$ are strictly increasing in $\lambda_c$. Then, from conditions (108), (109) and the fact that $\phi_\tau$ itself is strictly increasing in $\lambda_c$ for all $\tau \geq 2$, we have $\frac{\partial \phi_\tau}{\partial \lambda_c}$
and $\frac{\partial \omega}{\partial \kappa}$ are strictly increasing in $\lambda_c$ for all $\tau \geq 2$ by induction. The result then follows simply from letting $\tau = T$.

Consider now the environment studied in Section 7 and let us study the cross-partial derivative of the relevant fiscal multiplier with respect to $\kappa$ and $\lambda_c$. Similarly to conditions (107), (108) and (109), we have

$$\frac{\partial \phi_{g,1}}{\partial \kappa} = \sigma (1 - \Omega_c) > 0 \quad \text{and} \quad \frac{\partial \varpi_1}{\partial \kappa} = \beta (1 - \Omega_c) > 0.$$  

$$\frac{\partial \phi_{g,\tau}}{\partial \kappa} = (\beta + (1 - \beta + \sigma \kappa \Omega_c) \lambda_c) \frac{\partial \phi_{g,\tau-1}}{\partial \kappa} + \sigma \Omega_c \lambda_c \phi_{g,\tau-1} + \sigma \frac{\partial \varpi_{g,\tau-1}}{\partial \kappa},$$

$$\frac{\partial \varpi_{g,\tau}}{\partial \kappa} = \kappa \beta \lambda_c \Omega_c \frac{\partial \phi_{g,\tau-1}}{\partial \kappa} + \beta \lambda_c \Omega_c \phi_{g,\tau-1} + \beta \frac{\partial \varpi_{g,\tau-1}}{\partial \kappa}.$$

The result then follows from the same argument as before, in the case of forward guidance.
